It is noteworthy that the abovementioned fluid and variable process of self-conception contrasted with the dominant view of the self, which was portrayed as a unique and relatively fixed mental structure, stored in memory in an invariant state until activated by a specific circumstance, leading to consistent behavior despite situational variability (e.g., Markus and Wurf 1987). Turner and colleagues challenged this characterization and argued that rather than being preconceived and in a ready-to-be-activated state, self-concept is generated *reflexively* and on the spot to fit the perceiver's relationship to an ever-changing social context and reality. Context-driven category formation was posited to rely on an on-the-spot self-appraisal made possible by the recruitment of cognitive resources (e.g., long-term knowledge, implicit theories, cultural beliefs, social representations) that interacted with the specific set of instances being represented (Turner et al. 1994).

Formation of self-concept, at any instance, is proposed to be subjected to multiple salient categories that reinforce or conflict each other. Self-perception is thought to be influenced and shifted based on the relative strengths of competing self-categorizations at the personal and group level (Turner and Oakes 1989). The self-concept that emerges is therefore noted to reflect the compromise in self-perception made when choosing among several competing and alternative ways of categorizing the self in any given situation. Category salience is considered to be dependent largely on the interaction between accessibility (the readiness of a perceiver to use a particular category) and fit (the match between the category

and reality) within a given situation (Oakes 1987) and is thought to be reflective of an individual's past experiences, present expectations, and current motives, values, and needs (Turner et al. 1994). Accessibility of categorizations can be due to their frequent use (chronic accessibility) or relevancy to a particular situation (situational accessibility). Fit, which has two aspects, refers to whether categorization accounts for relevant similarities and differences between individuals or stimuli in a particular context as defined by the principle of meta-contrast (comparative fit) and whether categorization is based on beliefs and theories about the meaning of the category (normative fit).

Social Identity

Self-categorization theory substantially revised the conception of *social* identity. This was done by differentiating it from *personal* identity, stating that it can sometimes function to the relative exclusion of personal identity, and generated through a different level (of inclusiveness) of self-categorization. Prior to SCT, "social" selves and "social identities" were not regarded as selves that were in a subjective sense psychologically *shared* with others. Rather, "social" identity was considered to mean an outward impression that was perceived by others, whether or not it corresponded to the inner, private self. Terminology such as "global," "collective," "public," "interdependent," or "relational self" that existed in mainstream self-literature all referred to the *personal* self, meaning the self-concept as a representation or collection of representations of the perceiver as an *individual* person, understood to be different from other individuals (for a review, see Tyler et al. 2014). In sum, there was no self outside of the private, inner, idiosyncratic self.

Self-categorization theory postulates that perceiving ourselves through the lens of our social identity (e.g., in terms of "we" and "us"), as opposed to our personal identity (e.g., in terms of "I" and "me"), is a normal and authentic variation of the self, arising from the same general processes that give rise to personal self. Self-

conception at the social level is thought of as defining and experiencing the subjective self as similar or equivalent to a social group in contrast to another. When an individual experiences themselves through their social identity (as opposed to their personal identity), at that moment “the self is defined in terms of *others who exist outside the individual person doing the experiencing* and therefore cannot be reduced to personal identity. The self can be defined and experienced *subjectively* as a social collectivity (Turner et al. 1994, p. 454). The social collectivity becomes self, through a process known as *depersonalization*, which refers to individuals perceiving or defining themselves, and other members of primed social group, less as differing individual persons and more as interchangeable exemplars of the group prototype. Turner and colleagues argue that depersonalization is the psychological process underlying group behavior. Previous research has shown depersonalization as an explanatory variable for major group phenomena, specifically group formation and cohesiveness, cooperation, competition, social influence, social stereotyping, and crowd behavior (for a review, see Turner and Onorato 1999).

The notion of group *prototype* is important when considering group processes, as it represents fuzzy sets of attributes that define a group and its members and distinguish them from other groups by maximizing ingroup similarities and intergroup differences. Prototypes describe and prescribe group attitudes, beliefs, feelings, and behaviors that are appropriate in a given context, thereby generating stereotypical expectations and encouraging stereotype-consistent interpretation of ambiguous behavior. By accentuating intragroup similarities and intergroup differences, prototypes serve to define groups as distinct entities. Categories are however not defined by a fixed but rather *context-dependent* prototype, driven by the particular outgroup that is contextually salient and serving as a comparative point of reference or vary based on what dimension or attribute of the group gains importance. For example, as groups become more polarized (i.e., a group becomes more extreme in an intergroup setting), the more extreme members of that group will gain relative

prototypicality (Turner 1991), which in turn will shift the meaning of a self-category based on the contextually dependent change in its representative members. The fluidity of prototypes is yet another element that contributes to the variability of self-concept.

Conclusion

A shared social identity implies a shared mental representation of the self – a shift in self-concept from personal to social identity – which transforms and aligns thoughts, feelings, perceptions, and behaviors to group prototype, thereby engendering a sense of solidarity and connectedness which enables collective and unified behavior. From an evolutionary perspective, the transition of the self-concept, from personal to social (group persona), has many adaptive benefits that include, but are not limited to, positive ingroup attitudes and cohesion, cooperation, altruism, emotional contagion and empathy, collective behavior, and mutual influence (Hogg and Terry 2000). Group identification and group-related processes may have been fostered by our early evolutionary environment, in which individuals relied on group formation in order to gain greater access to resources, heightened defense against predators, and greater reproductive success (Buss and Kenrick 1998), all of which enhance survival and fitness. Given that individual survival is directly linked to group survival, the well-being and progress of any group are dependent on the engagement of its members in pro-social and cooperative behavior, in other words, the ability to compromise self-interest for the benefit of the group. Forgoing self-interest is conceivably contingent upon the ability to expand the sense of self – to be able to depersonalize and experience a sense of oneness with others – or the ability to see ourselves as interchangeable members of a social category. In this way, serving the group can be experienced as serving the self. The theory’s conceptualization of the self-concept, as variable, and able to operate at social or higher levels of inclusiveness, captures the psychological prerequisite for non-selfish mentality and

behavior. It may be our ability to shift our self-concept from personal to social that enables the generation of emotion such as *empathy* for strangers or non-kin members, as one can identify with or share a sense of self with any target, to the degree that merging point of relatedness can be conceived of.

Definition

The active misrepresentation of reality to the conscious mind in order to better deceive others

Introduction

After being introduced to evolutionary theory, Robert Trivers became interested in the

counterintuitive paradox of self-deception. How could natural selection simultaneously favor the evolution of complex sensory organs and fine-tuned detection mechanisms while also selecting for the systematic distortion of information once received by the brain. The more he learned about social evolution, the more he was convinced that the driving force behind the evolution to deceive oneself was selection pressure to be better able to deceive others (Trivers 1985). Given the intense psychological warfare observed in social creatures, Trivers argued that selection could act to favor various forms of reality manipulation that would benefit the individual. One result of this coevolutionary arms race Trivers suggests was the evolution of human intelligence; a very real cost, however, is the impaired ability to deal with reality (Cashdan and Trivers 2002, Trivers 1991, 1997, 2000, 2010, Trivers and Newton 1982).

Early Interest in Self-Deception

Trivers refers to self-deception as an important factor in human social interactions in early papers on reciprocal altruism and parent-offspring conflict, but it was in the forward to Richard Dawkins's *The Selfish Gene* that he first formalized his theory. Dawkins wrote extensively on the adaptive function of deception in nature, from avoiding predation via crypsis to frightening off predators using visually mimicry. If deception is an important part of animal communication, Trivers argued that humans, with their complex communication systems and big brains, must be under intense selection pressure to develop mechanisms to detect it, and therefore counterselection for self-deception as a strategy to avoid detection by rendering some facts unconscious, and thus less likely to betray the truth via subtle unconscious signals (e.g., sweat, increased heartbeat, galvanic skin response, change in micro-expressions, etc.) (Trivers 2011).

Development of an Evolutionary Theory of Self-Deception

Trivers developed a scientific theory of deceit and self-deception using evolutionary biology over

Self-Deception, Fig. 1 True (*T*) and false (*F*) information are simultaneously stored within an organism, but with a bias: the true is stored in the unconscious mind (*shaded area*), the better to deceive an onlooker (eye).

the next 40 years. He described fragmentation and conflict where true and false information are simultaneously stored in the brain with a bias toward the true information being stored in the unconscious and the false information in the conscious (Fig. 1) (Trivers 2002).

Trivers identified situations in which self-deception in the service of deceiving others would evolve as an adaptive strategy. Denying ongoing deception reduces the physiological costs of stress and cognitive load that are associated with deception, such as reduced immune function (Von Hippell and Trivers 2011). Being literally unaware that you are doing something, not only makes you less likely to be detected but also more sympathetic if you are caught. Self-promotion is also a major source of self-deception, where individuals tend to emphasize positive qualities and deemphasize their negative qualities. Humans are especially prone to self-deception in the construction of biased social theory and tend to view everything from personal relationships to the state of world

affairs from perspectives that portray themselves and their perspective in favorable ways (Trivers 2011).

Conclusion

Trivers' 2011 book *The Folly of Fools* provides a comprehensive overview of evidence in support of Trivers' theory of deceit and self-deception based on evolutionary logic. The functional view of lying to ourselves to more fluidly deceive others is supported with diverse lines of evidence from neurophysiology, immunology, parent-offspring relationships, genomic imprinting, sexuality and reproduction, and psychological studies on cognitive dissonance, confirmation bias, and aggression. Trivers provides many examples of self-deception in everyday life from the stock market to drug addiction and lie detector tests. He investigates the role of self-deception in air and space disasters and the use of false historical narratives to explore complex behaviors in groups and societies such as genocide, war, and religion (Trivers 2011).

[Intimate partner violence](#); [Male sexual jealousy](#);
[Physical aggression](#); [Retaliation](#); [Self-defense](#)

Definition

Whereas men use physical aggression against women to control women's sexual behavior, women typically use physical aggression against men to defend themselves from male attacks or to retaliate for long-term abuse.

Introduction

In many samples, men and women inflict physical aggression against one another with relatively equal frequency (Archer 2000). However, Archer (2000) reports that female-perpetrated violence against men is primarily nonlethal, whereas men's aggression against women is more likely to be lethal. A woman uses physical aggression against a man in self-defense and in response to her partner's violence, as retaliation for prolonged abuse, or because the woman does not see an alternative method to escape the abusive relationship (Buss 2006; Daly and Wilson 1988). Women are less likely than men to inflict physical aggression against a partner in retribution for that partner's infidelity (Wilson and Daly 1985).

Motivation for Violence

Women experience and respond to fear differently than men (Cross and Campbell 2011). Although fear sometimes motivates competitiveness and combativeness in men, women's fear more often inhibits aggression. Women respond to danger or threats more sensitively and carefully than men, although both sexes may have evolved psychological anti-homicide mechanisms to avoid physical injury and death (Buss 2006). Women are less prone to engage in physical violence, perhaps because the majority of child-rearing responsibilities fall to women, who therefore may have more to lose as a consequence of debilitating physical injury (Campbell 2013). Engaging in violent behavior and subsequently dying might be especially devastating for the survival prospects of a woman's offspring. Additionally, avoiding physical violence would be advantageous for women because fertilization and gestation occurs within women. Safeguarding the ability to successfully rear offspring may have been particularly important for women's ancestral reproductive success. Given strong selection pressures for women to avoid physical injury, female-perpetrated violence primarily occurs in situations in which women must protect themselves from extreme bodily harm or death.

Self-Defense

Female-perpetrated violence is often initiated in response to a male intimate partner's aggression against the woman. *Male* sexual jealousy is the primary reason women defend themselves from or kill their mates (Daly and Wilson 1988). Male sexual jealousy motivates men to use aggression against women to manipulate female sexual behavior (e.g., to dissuade the woman from committing infidelity or abandoning the relationship; Buss 2000; Smuts 1992). In response to physical aggression and the threat of homicide motivated by male sexual jealousy, women use violence to protect themselves, their current offspring, and their future reproductive opportunities. In fact, women's aggression is greater against intimate partners than against other targets and is typically associated with a disinhibiting situation that evokes aggression (Cross and Campbell 2011), such as contexts in which the woman is defending herself from a violent intimate partner. Additionally, Cross and Campbell (2011) reported that female-perpetrated aggression against men peaks between the woman's ages 15–19 years. Women within this age range have maximum reproductive value or expected future reproduction. Given the importance men place on fertility and youth in a long-term partner, men are more likely to respond violently to a younger (and therefore more reproductively valuable) partner's desertion or infidelity (Buss 2006; Daly and Wilson 1988). Thus, younger women are more likely to use violence to defend themselves against sexually jealous male partners.

Retaliation

Outside the context of defense from a partner's violent attacks, it may have been ancestrally beneficial for a woman to kill or to use violence against her partner. A woman who kills her partner after experiencing his violence over an extended period may eventually kill him to permanently end the abuse or to protect her children. For example, Daly and Wilson (1988) report that wives kill their husbands after prolonged and severe intimate partner abuse, when they reside closer to their genetic relatives, and when their children are threatened or abused. Women retaliate when

they are not able to identify an alternate strategy to escape their abusive partner. Unlike men, who often use partner-directed violence to coerce and control a partner, women use partner-directed violence (including homicide) to escape a dangerous partner or to seek retribution for previous and ongoing physical violence against them or their children.

Additionally, in rare instances, women kill their partner for suspected or actual infidelity. Although jealousy-motivated partner-killing is more often committed by men against women, some women cite jealousy as the primary motivator for killing their partner (Daly and Wilson 1988). For example, of all homicides in Detroit in 1982, 58 were related to marital conflicts and 20 of these were completed by women (Wilson and Daly 1985). Of these 20 homicides, six women killed their husband because of his infidelity. Women may be less likely than men to kill their partners in response to a real or suspected infidelity because women cannot be duped into investing in a genetically unrelated offspring – that is, a partner's infidelity may be less reproductively costly for women than for men. However, partner-killing may be beneficial for women in cases in which killing the husband would halt allocation of his resources to a female rival and her offspring.

Conclusion

Women perform most child-rearing duties and invest more heavily in offspring than do men. Thus, women may have more to lose by engaging in or experiencing physical violence. Although women benefit less by perpetrating violence than do men, women use aggression strategically to physically defend themselves from jealous mates, to escape abusive relationships, to retaliate for prolonged abuse, to protect offspring, and, occasionally, to punish or prevent a partner's infidelity.

Self-Efficacy, Animal Phobias, and Evolutionary Mismatch

Jiaqing O.
Department of Psychology, Aberystwyth
University, Aberystwyth, Ceredigion, UK

Synonyms

[Interpretation about one's competence and aversions of certain living organisms; Perception of one's capability and extreme fears of some creatures](#)

Definition

The judgment one has about his/her own competence to cope with certain feared animals is believed to have been an adaptive psychological mechanism that has assisted humans in their attempts to avoid serious harm (and therefore enhancing their survival chances) throughout evolutionary history. Nevertheless, such an evolved psychological mechanism is conceivably less relevant in the modern, largely urbanized and medically progressive environment whereby the risk of being severely injured by the dreaded creatures is relatively more modest.

Introduction

Self-efficacy, the perception of one's proficiency in accomplishing tasks that are related to the achievement of a specific goal (Bandura 1977), is a concept that has garnered considerable empirical endorsement and has been successfully utilized in elucidating an extensive range of phenomena over the years (Pajares 1997). One of the most intriguing of these applications pertained to the topic of phobias (e.g., the extreme distress associated with encountering some dreaded situations/objects) in humans (Bandura 1977). A phobia, or more specifically an animal phobia in this case, was contended to develop when one has appraised that he/she would not have the competence to ensure his/her own well-being in the presence of the specific animal (Williams 1992). For instance, if an individual has reached the conclusion that he/she would not have the agility to dodge an attack by a nearby snake or the strength to prevent being grievously harmed by it, then he/she is likely to be immensely afraid of it.

Self-Efficacy: An Adaptive Mechanism Against Animal Threats

Taking into account the apparent ubiquitousness of both self-efficacy and the extreme apprehension toward certain creatures around the world

(Davey et al. 1998; Scholz et al. 2002), it is logical to assume that self-efficacy must have evolved in humans as a psychological mechanism which has provided useful information for an individual about his/her own capability to deal successfully with any possible threat (e.g., any likely danger that might have been posed by a particular animal in this case) and how to react accordingly across prehistory. On occasions (or even possibly quite regularly), although such a mechanism (when utilized specifically in the domain of animal threats) might result in undue fears and unnecessary avoidance (e.g., when an animal is actually harmless), the price that one might pay (e.g., death) for making a careless mistake (e.g., being self-assured, and therefore calm, about one's competence to handle a venomous snake) is so high that it would have been adaptive for humans to develop more generalized phobias about certain creatures (e.g., an excessive fear toward all snakes just to be safe) (Nesse 1994). Indeed, empirical data to date have broadly supported the suggested role of self-efficacy in the manifestation of zoophobia symptoms (e.g., Johnstone and Page 2004), and the notion that such apprehensive reactions were typically excessive (e.g., Jones and Menzies 2000).

Evolved Self-Efficacy and Zoophobias in the Modern World

The utility of self-efficacy as an evolved psychological mechanism in coping specifically with animal threats has largely dwindled in the present world however, as a result of massive societal/technological and medical transformations in the recent era. For instance, a huge proportion of the human race is presently located in urban settings (as opposed to more natural surroundings), which are environments whereby encounters with potentially dangerous animals are considerably much more uncommon (United Nations 2014). In addition, significant advances in medical research and treatment have likewise greatly reduced the lethality of an attack by any feared animal (e.g., Dart et al. 2001). In fact, humans are much more likely to die under

modern technology-related circumstances (e.g., in a vehicular accident) as compared to an attack by a feared creature in the current world, although most are still likely to be more apprehensive of the latter due to the vast amount of time psychological mechanisms (e.g., animal coping self-efficacy) would generally require to adapt to evolutionarily novel objects/conditions (Nesse 1994).

Conclusion

Self-efficacy is interpreted to be an evolved psychological adaptation that has played a pivotal role in influencing relevant coping reactions (e.g., be extremely fearful or remain relatively calm) toward a diverse array of potential threats (e.g., animals) across prehistory by virtue of a pertinent assessment about one's survival risk (if threatened by a particular creature) in relation to his/her own capability. Such an adaptation, specifically in the context of zoophobias, might nonetheless be considered excessive in the current environment given the radical introduction of evolutionarily-novel technologies and medical treatments in the modern, predominantly urbanized world.

Self-Enhancement Relative to Others

Aleksandra Pilarska
Institute of Psychology, Adam Mickiewicz
University, Poznań, Poland

Synonyms

[Group-serving biases](#); [Self-other bias](#); [Valuation motive](#)

Definition

Self-enhancement refers to a group of psychological phenomena whose common feature is holding a tendentiously favorable view of oneself. Given the fact that an individual's self-view is largely socially constituted, one's relationships with others greatly influence self-evaluation. This interpersonal aspect of self-esteem regulation can be observed especially well in phenomena such as the better-than-average effect and in-group favoritism and in various self-evaluation maintenance strategies specified by Tesser's (1988) self-evaluation maintenance model.

Introduction

The idea that people strive to feel good about themselves is a part of folk psychology. Scientific evidence accumulated over the past decades attests to the prevalence and cross-cultural universality of this need. This entry is a brief delineation of the main themes emerging from the literature on self-enhancement in relational context, including the possible evolutionary bases of the self-enhancement motive.

Self-Enhancement and Relationships with Others

People's desire to sustain or enhance a positive self-view has been widely documented and suggested as determining a broad range of human behavior. For example, individuals tend to see themselves as better than most other people, and they tend to evaluate more favorably members of their own group than the out-group. The former effect, known as the better-than-average effect (also referred to as the self-other bias), was first identified over four decades ago (e.g., Codol 1975) and is regarded as the most robust of all self-enhancement phenomena. Further studies have revealed four general types of moderating factors that alter the effect's strength: the scales on which the effect is measured (i.e., the effect is stronger when ratings come from direct scales

than when they are derived from separate scales for the self and an average peer), the nature of the judgment dimension (i.e., the effect is stronger when the attributes being compared are controllable or ambiguous rather than uncontrollable or unambiguous), the nature of the comparison target (i.e., the effect is stronger when comparisons involve specific and real individuals rather than hypothetical targets such as an average peer), and characteristics of the judge (i.e., individual differences such as depression affect the tendency to evaluate oneself more favorably than others) (Alicke and Govorun 2005). It is also worth noting that the perception of being better than the average person can be achieved either by overestimating one's own positive traits or by underestimating one's negative traits. A preference for these strategies differs among narcissists and individuals with genuine high self-esteem: whereas narcissists tend to self-enhance by augmenting their positive aspects, those with genuine high self-esteem are more prone to bolster self-worth through the more socially accepted discounting of negative traits (Hovrath and Morf 2010).

The latter effect, that is, the in-group favoritism (otherwise known as the in-group superiority), can be thought of as an extension of the self-other bias to social self. In-group favoritism has been shown to occur in naturalistic groups (e.g., one's ethnic or religious group) as well as in experimentally manufactured groups (e.g., Masuda and Fu 2015). Indeed, the so-called mere categorization effect, where the mere labeling of people as "us" and "them" results in an in-group favoritism, has been one of the most reliable findings in social psychology (e.g., Brewer 1979).

Both the self-other bias and the in-group favoritism represent direct forms of self-enhancement, since individuals are directly claiming a superior status for the self. Such forms of self-enhancing biases are exhibited to a greater extent by people with high self-esteem than by people with low self-esteem. Low self-esteem individuals, who doubt their capacities in many areas, tend to engage in indirect forms of self-enhancement, which means they use their relationships with

others to promote feelings of self-worth (Brown et al. 1988). Indirect self-enhancement strategies include connection-focused tactics of boasting (i.e., proclaiming a positive link to a favorable other), burying (i.e., disclaiming a positive link to an unfavorable other), blaring (i.e., proclaiming a negative link to an unfavorable other), and blurring (i.e., disclaiming a negative link to a favorable other) and other-focused tactics of burnishing (i.e., enhancing the favorable features of a positively linked other), boosting (i.e., minimizing the unfavorable features of a positively linked other), blasting (i.e., exaggerating the unfavorable features of a negatively linked other), and belittling (i.e., minimizing the favorable features of a negatively linked other; Cialdini 1989). Favorable self-other and in-group/out-group comparisons may also be considered as examples of comparative self-enhancement strategies that are generally more prevalent among narcissists than among nonnarcissists. Non-comparative techniques (e.g., strategically evaluating the importance of the task) do not distinguish as readily narcissists from non-narcissists (Campbell et al. 2000).

An interpretive mechanism for understanding how others affect an individual's self-evaluation is provided by Tesser's (1988) self-evaluation maintenance model. The model assumes that people's self-evaluation is determined by two antagonistic processes: a reflection process and a comparison process, both of which have as component variables the closeness of the relationship with the comparison other, the quality of the comparison other's performance, and the self-relevance of the performance domain. The better the other's performance and the closer the psychological relationship, the more one can gain in self-evaluation through the reflection process (this is the basking in the reflected glory effect mentioned earlier), yet, at the same time, the more one can lose in self-evaluation through the comparison process. The relative importance of the reflection and comparison process is dependent upon the self-relevance of the performance domain: when relevance is high, individuals are likely to engage in comparison and suffer decreases in self-evaluation. To

prevent the loss in self-evaluation, one can either alter the closeness of the relationship with the comparison other (e.g., distance oneself from that other), alter the importance of the performance domain to one's self-definition (e.g., decide that the domain is simply no longer self-relevant), or alter own or the other's performance (e.g., sabotage the other's efforts). All these strategies have been extensively explored in the context of social interactions and close relationships (e.g., Tesser 1988). Also, previous studies found support for the role of several factors, including chronic self-esteem, as moderators of the responses to social comparisons (e.g., Beach and Tesser 1995).

It has been long debated whether a robust self-enhancing tendency fosters or hinders psychological well-being. Paulhus (1998) attempted to empirically reconcile the divergent findings in the literature and provided evidence that self-enhancement is adaptive with regard to intrapersonal functioning (e.g., having a positive self-attitude), but not interpersonal functioning, at least in the long run. Initial positive impressions self-enhancers generate wear off after increased acquaintance.

Self-Enhancement in an Evolutionary Context

Self-enhancement is thought by many to be a universal force of human behavior (e.g., Sedikides et al. 2004). Its prevalence and cross-cultural occurrence suggest the possibility that the motive has been evolutionarily selected because it conferred a survival advantage. Sedikides et al. (2004) describe ecological (e.g., food acquisition) and social (e.g., intragroup interactions) pressures that likely facilitated the capacity to make self-evaluative judgments and to use tactics of impression management and led to the evolution of self-enhancement. The potential evolutionary utility of self-enhancement strivings is to promote the adaptiveness of an individual's self-system (e.g., by leading one to select tasks with a high probability of success), improve an individual's ability to interact with others (e.g., by increasing one's

perceived mate value), and benefit an individual's standing in the group as well as the group itself (e.g., by promoting one's chances to attain a leadership position; Sedikides et al. 2004). The notion that self-enhancement evolved as a psychological solution to the adaptive problem of tracing one's position within a group hierarchy and one's relational value to others is reflected in Barkow's (1989) and Leary et al.'s (1995) works. Apart from these social advantages, self-evaluation maintenance processes could also be seen as helping individuals to identify and create relatively unique spheres of competence within the primary social group (Beach and Tesser 2000). The evolution of self-enhancement has also been explained by Pyszczynski and colleagues' (2004) terror management theory to be due to the buffering effect of self-esteem on the fear of death.

Several authors have studied the evolution of in-group favoritism, widely observed in non-humans as well (e.g., Masuda and Fu 2015). Evolutionary models of in-group favoritism typically rely on mechanisms of cooperation, which implicitly assume material payoff maximization and affective empathy. Of particular interest in this context are processes of cultural group selection, which explain why groups composed of altruists outcompete groups of selfish individuals (Mesoudi and Jensen 2012). As suggested by Habermacher (2015), self-enhancement may function to direct and restrict altruism and compassion. That is, humans could have evolved to have depersonalized and generalized altruistic motivations, but self-enhancing biases – as ad hoc adaptations – helped to contain within the group their beneficial effect.

Conclusion

Self-enhancement has received much theoretical attention, and the empirical evidence that people strive for self-esteem is voluminous and compelling. In evolutionary context, various manifestations of self-enhancement might have promoted successful adaptation to group life and offered considerable survival and reproductive advantages.

Definitions

Self-esteem denotes the positivity of one's overall self-evaluation. Status denotes the social prestige one gains in virtue of being respected and admired. Dominance theory and hierometer theory, drawing on evolutionary theory, specify how self-esteem and status might interrelate.

Introduction

Human beings, as self-conscious animals, evaluate themselves positively or negatively. In addition, as social animals, they also evaluate one another positively or negatively. The former type of evaluation, when positive, is commonly known as *self-esteem* (Rosenberg 1965). The latter type of evaluation, when positive, might be labeled “social esteem.” One important question is how the two are linked.

Everyday intuition suggests, and classic theories propose, that self-esteem derives from social esteem (Cooley 1902). However, people do not absorb social information passively, but actively process it in a manner that protects their self-esteem (Sedikides and Gregg 2008). In addition, whereas self-esteem is inherently unitary – the self as a whole being a singularity – social esteem is inherently complex. Three fundamental dimensions stand out. First, people may be accorded

respect and admiration, in virtue of being competent or powerful (*social status*; Fiske 2010). Second, people may be liked and appreciated, in virtue of being cooperative and caring (*social inclusion*; DeWall et al. 2011). Third, people may be fancied and pursued, in virtue of being fertile or rich (*reproductive fitness*; Shackelford et al. 2005).

Several theories address the link between social esteem and self-esteem and the evolutionary function that this link might serve. However, the theories differ in focusing on one or another of these three fundamental dimensions of value. For example, *sociometer theory* (Leary et al. 1995) in its original form focuses on social inclusion, but later extensions of the theory to romantic relationships focus on reproductive fitness (Bale and Archer 2013). Here, we discuss two theories that focus on social status as a fundamental dimension of value: *dominance theory* and *hierometer theory*. Both theories claim to identify aspects of mind and behavior that have arisen in response to recurrent adaptive challenges present in the human ancestral environment.

Dominance Theory

Dominance theory (Barkow 1980) seeks to explain the striving for self-esteem in human beings as an elaboration of the more primitive strivings for social ascendancy in nonhuman animals. Most animal societies are hierarchically organized (Pusey and Packer 1997); that is, conspecifics spontaneously rank order themselves in ways that determine their priority of access to resources and mates. Doing so permits members of those societies, whatever their rank, to avail of the adaptive advantages of reduced aggression (Kaufmann 1983). Human societies are likewise stratified (Fiske 2010). However, given the greater cognitive sophistication of human beings (Gregg and Sedikides 2018), the mental mechanisms underlying their social stratification, although still shaped by evolutionary forces, are also liable to contain novel elements.

Dominance theory starts with the observation that rank order in animals can be largely characterized in terms of behavioral *dominance* or *submission*. Whether through differences in ability, motivation, or personality (Hurd 2006), some animals succeed in asserting themselves over others, often through ritualized signaling instead of overt aggression. Accordingly, each animal's rank order comes to reflect their level of comparative success in asserting themselves over time. Moreover, given the overall adaptive advantages of occupying a higher rank, it is plausible that some dedicated drive evolved to motivate animals toward seizing opportunities, when available, to attain this rank. Human beings should be no exception to this rule – and indeed, there is ample evidence of a universal desire for social status among them (Anderson et al. 2015). However, given that human beings are also self-conscious organisms, who contemplate themselves as well as their environment, dominance theory postulates that the impulse to physically prevail over other animals has been largely transformed into an impulse to *symbolically evaluate oneself as better than other people* – which dominance theory characterizes as self-esteem. However, it should be noted that this definition of self-esteem – perceived relative superiority – differs from standard definitions of self-esteem, which involving seeing oneself as individually possessing adequate worth (Rosenberg 1965).

Dominance theory also specifies likely antecedents of self-esteem. Given that human beings are cultural animals (Baumeister 2005), their capacity to please real or imagined others (including, in aboriginal societies, ancestors and gods), by meeting expectations that are normative in their societies, is likely to be one key antecedent. Doing so can be understood as a means of gaining *prestige* in the eyes of others, as opposed to attempting to achieve dominance over them using raw power (De Waal-Andrews et al. 2015). Thus, whereas for most nonhuman animals (with possible exceptions among higher primates such as chimpanzees or bonobos), their rank in the social hierarchy is *only* the result of power-mediated dominance; in humans it can *also* be

the result of consensus-mediated prestige. For this reason, indeed, dominance theory might be better labeled “prestige theory.” The drive for dominance is what human self-esteem evolved out of, not what currently underlies it.

Hierometer Theory

Like dominance theory, hierometer theory (Mahadevan et al. 2016) also postulates that self-esteem rises and falls in tandem with higher or lower social status. However, it differs from dominance theory in the account it gives of the adaptive function of self-esteem and of the motivational goals being pursued. In general, whereas dominance theory invokes an absolute drive toward social status, hierometer theory invokes a contingent one.

Hierometer theory starts from the premise that, although higher social status may be generally more conducive to survival and reproduction than lower social status, it is nonetheless *not* generally adaptive for people to strive perpetually for higher social status, by invariably and inflexibly seizing opportunities to contest their place in the hierarchy. The simple reason is that such contests can be lost as well as won; and with one’s survival potentially at stake, the avoidance of catastrophic defeats is no less imperative as the securing of profitable victories. Accordingly, the decision as to whether or not to enter such a contest, if it is to be optimally adaptive, must depend on people’s actual competitive prospects, as best they can be determined. The situation is analogous to that arising in poker: all else equal, it makes more sense to raise when in possession of a relatively good hand and to fold when in possession of a relatively poor one. Hierometer theory postulates that the quality of one’s poker hand corresponds to one’s *existing* social status. Specifically, when one’s social status is high, it makes more sense to escalate an incipient conflict assertively, whereas, when it is low, it makes more sense to de-escalate it acquiescently. This is because being already respected and admired (in a prestige hierarchy; or alternatively, being feared and

obeyed in a dominance hierarchy) is a reliable sign that one has at one’s disposal sufficient material and social resources to compete successfully. Accordingly, behavioral assertiveness should covary with social status. How does self-esteem fit into this picture? Hierometer theory postulates that self-esteem evolved at least in part as a psychological variable to mediate between the two – by reflecting social status on the one hand, and by regulating behavioral assertiveness on the other.

Note that, unlike dominance theory, hierometer does not specify the achievement of higher self-esteem per se as the motivational goal (although it does not deny the possibility). Rather, hierometer theory postulates that self-esteem *moderates* levels of motivation to escalate conflict so as to optimize people’s chances of navigating social hierarchies. Another way of putting this point is to say that, whereas dominance theory characterizes the achievement of self-esteem as a symbolic proxy for the achievement of behavioral dominance, hierometer theory characterizes the achievement of self-esteem as the result of having previously attained higher social status, which in turn facilitates the expression of assertive or “dominant” behaviors. A further implication is that, whereas dominance theory implies a *compensatory* dynamic – people will strive for self-esteem or prestige if they perceive one or the other to be too low (sociometer theory makes similar claims in respect of social inclusion; Leary et al. 1995), hierometer theory implies a *consolidatory* dynamic – people will strive for social status (via assertive behavior) to the extent that they already possess it.

Hierometer also goes further in postulating a role, not only for self-esteem but also for a variant form of self-regard, namely, *narcissism*, conceived of as normally distributed trait as opposed to a discrete clinical condition (Foster and Campbell 2007). Narcissism is characterized by grandiose self-views and exhibitionistic displays, an interest in exercising power and authority, and a tendency to feel entitled and to exploit others (Ackerman et al. 2011). As such, it is nonetheless potentially suited to mediating the impact of social status on competitive behavior.

Empirical Evidence for the Link Between Social Status and Self-Esteem

Despite the differences between dominance theory and hierometer theory, they make an identical prediction with respect to the link between social status and self-esteem (or narcissism): levels of the former should covary with levels of the latter. Moreover, this prediction should be borne out whether both variables are measured as traits or states as well as when confounding factors are taken into account.

Across diverse literatures and samples, the predicted positive correlation between social status and self-esteem emerges. For example, Faunce (1984) found that the social status of high-school students in their class, as reflected in peer rankings, especially when given by best friends, strongly predicted their self-esteem. Similarly, Smith et al. (1998, Study 3) found that, among university students, the belief that they were accorded respect by most members of their university community strongly predicted their self-esteem.

Nevertheless, given that social status covaries with other antecedents of self-esteem – in particular with social inclusion – such zero-order positive correlations are open to alternative interpretation. However, several studies have also confirmed that social status predicts self-esteem more specifically. For example, Fournier (2009) found that, among high-school students, peer ratings of respect, prominence, and influence predicted self-esteem even after controlling for peer ratings of likability and personal ratings of social support. In addition, Huo et al. (2010) found, in a similar populations, that social status (bundled with peer approval) predicted self-esteem (bundled with mental health) independently of social inclusion. Using cleaner operationalizations, Mahadevan et al. (2016) likewise found that social status predicted self-esteem independently of social inclusion. Furthermore, the link persisted even after controlling for the clinical confounds of depression and anxiety. Finally, only higher social status, but not higher social inclusion, independently predicted higher narcissism, thereby highlighting the value of

operationalizing self-regard in more than one way and pointing to a unique functional role for social status and narcissism.

Although dominance theory and hierometer theory imply that social status – again, defined as the respect and admiration afforded by others (Anderson et al. 2015) – should predict self-esteem, they also imply that the objective foundations of social status, in particular, factors such as income, education, and occupation, often termed *socioeconomic status* (SES), should also predict self-esteem. A meta-analysis by Twenge and Campbell (2002) indeed established that SES exhibits a small positive correlation on self-esteem. More recently, Kraus and Park (2014) reported that family income and personal education weakly predicted self-esteem but also that the effect was wholly mediated by subjective perceptions of one's social standing.

The best evidence for the impact of social status on self-esteem is experimental.

Wojciszke and Struzynska-Kujalowicz (2007, Study 2) showed that participants, assigned the group task of deciding which of several candidates should be hired for a job, ended up with higher state self-esteem after being randomly assigned to the role of a supervisor as opposed to a subordinate. Similarly, Leary et al. (2001, Studies 1 and 2) orthogonally manipulated social status and social inclusion by providing lab participants with false feedback about how many of their groupmates had nominated them as a group leader or as group member, respectively. Both manipulations exerted roughly equal effects on state self-esteem, in the expected directions. Finally, Mahadevan et al. (2018) conducted two experiments in which college students were led to anticipate, on the basis of credible but bogus tests of intellectual and emotional competence, that their future social status and social inclusion would be markedly either high or low relative to most of their peers. Care was taken to otherwise match the format and content of feedback delivered. Again, both manipulations exerted roughly equivalent effects on self-esteem. However, raising perceptions of future social status lead to a greater increase in narcissism than raising perceptions of future social inclusion did. This again

suggests that narcissism may be a more specific tracker of social status.

Hence, on the basis of converging evidence of varying methodological strength, social status and self-esteem, as well as narcissism, are linked in the manner predicted by both dominance and hierometer theory.

Conclusion

Within limits, how individuals are regarded by others affects how they regard themselves. Among other things, being respected and admired – enjoying social status – leads individuals to like themselves more, to have higher self-esteem, or even narcissism. Two theories, dominance theory and hierometer theory, both make this prediction, each offering an evolutionary rationale for it. However, they differ on the precise role they ascribe to self-esteem or narcissism, and how levels of status striving might be subsequently affected. Nonetheless, the initial prediction they make enjoys good empirical support. Most compellingly, experiments indicate that manipulations of social status exert a unique impact on self-esteem and narcissism and find that the effects observed are comparable in size to those observed for manipulations of social inclusion (which concurrently support sociometer theory). Accordingly, there are solid grounds to propose that the function of self-esteem and narcissism might be, at least in part, to track levels of social status and possibly as a prelude to regulating subsequent status-seeking behavior.

Synonyms

Sociometer; Sociometer theory

Definition

Sociometer theory suggests that self-esteem functions as a mechanism by which individuals track

their relational value (i.e., status) to others. Therefore, individuals who are high in self-esteem tend to be held in high regard.

Introduction

As a species, it is vital for an individual to have a good understanding of where he or she stands in relation to one's peers and to be able to accurately assess his or her status in a social hierarchy. This understanding allows the individual to reap the benefits of increased cooperation and opportunities for reciprocal altruism, along with increased mating opportunities. Alternatively, a misunderstanding of one's status would be detrimental. Therefore, it seems likely that not only would individuals be motivated to accurately assess their social status but that there would also be evolved mechanisms to facilitate this process. Indeed, it has been proposed that self-esteem acts as a status-tracking mechanism such that high self-esteem is indicative of higher status and inclusion among peers, whereas low self-esteem would reflect lower status in the group (Leary et al. 1995). A historical perspective on sociometer theory will be provided, followed by a discussion of the connections between sociometer theory and various outcomes (e.g., romantic relationships), and will close with a discussion of new developments in sociometer theory.

Perspectives on Self-Esteem

In the current research literature, self-esteem is often defined as the evaluative aspect of the self that is concerned with the degree to which people like themselves (Brown and Marshall 2006). In other words, self-esteem reflects the amount of worth and value an individual places on himself or herself. Thus, individuals with higher levels of self-esteem are more likely to view themselves in a relatively favorable light, whereas individuals with lower levels of self-esteem will tend to view themselves more negatively or at least be uncertain about their self-

views. High self-esteem has been found to be associated with a variety of important life outcomes (e.g., psychological well-being). In contrast, low levels of self-esteem have been shown to be associated with an array of negative outcomes (e.g., criminal behaviors; see Zeigler-Hill 2013, for a review). Despite the associations linking self-esteem with various important life outcomes, there has been a great deal of debate in recent years concerning the value of self-esteem with some researchers continuing to argue that self-esteem is an important construct (e.g., Zeigler-Hill 2013), whereas other researchers have adopted a much more negative view of self-esteem and consider it to be an epiphenomenon that has – at best – limited value (e.g., Baumeister et al. 2003).

This conflict over the importance of self-esteem can be resolved when a more nuanced approach to self-esteem is taken. More specifically, researchers have recognized that it may be important to account for aspects of self-esteem beyond its level because individuals with high levels of self-esteem appear to be a heterogeneous group consisting of those with *secure* high self-esteem and those with *fragile* high self-esteem (see Jordan and Zeigler-Hill 2013, for a review). Secure high self-esteem reflects positive attitudes about the self that are realistic and resistant to threat, whereas fragile high self-esteem refers to feelings of self-worth that are vulnerable to challenge and require constant validation. This distinction between secure and fragile forms of self-esteem adds depth to our understanding of self-esteem in that it helps us to understand how self-esteem level might fluctuate in the short term following different types of feedback. In turn, this has helped to elucidate previously conflicting findings. However, understanding secure and fragile self-esteem does not address the function and purpose of self-esteem. The question of the purpose of self-esteem is at the core of sociometer theory (Leary et al. 1995). The central premise of sociometer theory is that self-esteem functions as a status-tracking mechanism which provides important insights into the purpose and development of self-esteem.

Introduction to Sociometer Theory

The sociometer theory was developed in an attempt to provide an explanation about the purpose of self-esteem (Leary et al. 1995). More specifically, the concept of affiliation has an evolutionary foundation because relationships with other people have been important for human survival, reproduction, and the survival of offspring over the course of evolutionary history. For example, maintaining close proximity to other people has offered individuals with protection and opportunities to effectively solve social issues (Leary 2010). The driving force behind the self-esteem system is the fundamental need to associate with other people and build relationships that are strong and lasting (Stinson et al. 2015). This perspective states that the self-esteem system is developed in order to protect people from the negative consequences of social exclusion by monitoring the social environment for signals concerning social acceptance and social rejection (Leary 1999, 2010).

According to sociometer theory, self-esteem has a *status-tracking property* such that an individual's level of self-esteem depends on his or her relational value. Sociometer theory argues that self-esteem is an evolved regulatory system and adaptation that helps people establish and sustain meaningful relationships (Leary et al. 1995; Stinson et al. 2015) by allowing individuals to monitor the degree to which they are valued by others. In essence, self-esteem serves as a gauge that alerts individuals to either gains in their relational value (accompanied by increases in self-esteem) or losses in their relational value (accompanied by decreases in self-esteem). An important element of the sociometer theory is that changes in self-esteem may trigger compensatory mechanisms. For example, individuals who perceive a decrease in their state self-esteem should be motivated to engage in compensatory behaviors – such as being nicer to other people – in an effort to increase their relational value. A central tenet of sociometer theory is that people do not actually care about self-esteem for its own sake. Rather, self-esteem is only important because it indicates the degree to which

individuals are valued by others in their social environments (Leary et al. 1995). Sociometer theory provides a reason for self-esteem and moved away from previous approaches that simply suggested that individuals have an inherent need to feel good about themselves. Sociometer theory suggests that self-esteem functions as a means to motivate individuals to act in ways that increase their acceptance and decrease the likelihood of rejection within their social groups. That is, boosting self-esteem is not the ultimate objective but is simply a consequence of increasing relational value and avoiding rejection (Leary 1999, 2010).

Consistent with sociometer theory, a large number of studies have shown that self-esteem is responsive to social acceptance and rejection (e.g., Leary et al. 2001). The majority of sociometer research has focused on the consequences that acceptance and rejection have on mood and state self-esteem (e.g., Leary et al. 2001), but there have been attempts to expand sociometer theory in various ways such as by examining the implications of this perspective for social decision-making (Anthony et al. 2007). When making a social decision, people calculate the probability of social rewards (e.g., developing a new friendship) versus social costs (e.g., experiencing a rejection). People either engage in self-enhancing behaviors (e.g., seek social experiences) in order to achieve social awards or self-protecting behaviors (e.g., avoiding social experiences) in order to limit social costs (Baumeister et al. 1989). The sociometer monitors relational value in one's environment, but the resting point of the sociometer (i.e., self-esteem level) may impact one's relational value. For example, people with high self-esteem are more secure with their relational value and have a higher threshold for acceptance. As a result, people with higher levels of self-esteem are more likely to exhibit self-enhancing behaviors by forming new relationships regardless if there is a direct sign of group acceptance (Anthony et al. 2007). In contrast, people with low self-esteem are more likely to display self-protection behaviors because they anticipate rejection. As a consequence, people with lower levels of self-esteem avoid forming new

relationships unless there is a direct sign that the group will accept them (Anthony et al. 2007). It appears that people with low self-esteem are more reluctant to form relationships because of their fear of rejection. However, this need to protect one's empty relational value can be disregarded with unambiguous proof of acceptance. In sum, these findings support that the calibration of the sociometer is derived from acceptance and rejection in one's environment and directs one's social behavior (Anthony et al. 2007).

Multiple Domains

Individuals are able to function in a wide variety of environments that have different adaptive problems and these problems entail different solutions. A single sociometer or gauge may be ineffective at detecting an individual's relational value in different social environments. For example, a sociometer that monitors relational value in romantic relationships may be helpful for assisting a person's mate-selection strategies, but not for indicating a person's relational value in his or her workplace (Kirkpatrick and Ellis 2001). As a result, Kirkpatrick and Ellis (2001) proposed that self-esteem is not a unitary construct and that natural selection may have designed multiple psychological mechanisms for monitoring relational value in different social environments (i.e., domain-specific sociometers). However, the question regarding how many different sociometers in fact exist remains unanswered, but any interpersonal relationship that is important for survival may have a distinct sociometer (e.g., instrumental coalitions, mating relationships, familial relationships; Kirkpatrick and Ellis 2001).

Hill and Buss (2006) argue that self-esteem is not a unitary construct because it may be too limited to capture the numerous adaptive problems that individuals are likely to encounter. Rather, they suggest that self-esteem consists of a number of psychological components (e.g., internal representations, monitoring mechanisms, updating mechanisms, evaluative mechanisms, motivational mechanisms, mechanisms to generate output). More specifically, the first

psychological element to self-esteem is the ability to maintain *internal representations* of one's own capabilities. Maintaining an awareness of one's abilities allows the individual to compare oneself to other people during ambiguous situations and to make careful behavioral decisions. The ability to have *monitoring mechanisms* that are domain-specific provides an individual with cues about potential changes in one's relational value in different environments. This is important because an individual's ability to solve adaptive problems may change over time due to past experiences (e.g., the birth of a child). When the monitoring mechanisms detect a success or failure, it informs the *updating mechanisms* component of this new information which results in changes of internal representations. The fourth aspect of self-esteem is *affective evaluation* and this component is designed to evaluate internal representations. For example, trait self-esteem occurs when the affective evaluation consists of stable repetitions, as opposed to state self-esteem, which is an evaluation of updates or fluctuations. According to Hill and Buss (2006), none of these psychological mechanisms would exist without some motivational aspect. The affective evaluation component of self-esteem motivates people to engage in behaviors regarding their newly updated internal representations. The last component of self-esteem is the specific behavioral output and this underpinning takes into account that behavioral solutions are expected to change.

In addition, Hill and Buss (2006) further extended the theory regarding domain-specific sociometers by suggesting that attributes in one domain may contribute to successes in different domains. For example, good health increases an individual's value as a mate but may also have implications for perceptions of that individual as a friend and family member. If an attribute is specific to a domain, then it will be positively correlated with that domain and weakly correlated with other domains (Kavanagh and Scrutton 2015). An example is the attribute of physical attractiveness which plays an important role in the mating domain, but is not viewed as essential in other domains (e.g., coalitional domain; Cottrell et al. 2007). Attributes that contribute to multiple

domains may explain why self-esteem level has been found to be positively associated with different facets, and this approach may serve as a way to distinguish between domain-specific and domain-general attributes (Hill and Buss 2006).

The Mating Sociometer

From an evolutionary standpoint, selecting and retaining a mate is a primary concern (Buss 1988). Socially speaking, entire holidays and rituals have developed around mating. Furthermore, a large number of studies have been conducted to examine the factors that influence the selection and retention of mates (e.g., Buss 1988). These studies have revealed that individual differences – such as self-esteem – play a role in these processes. Furthermore, in accordance to sociometer theory, self-esteem level can be seen as an indicator of mate value (Holden et al. 2014).

After a mate has been selected, the next challenge for successfully rearing offspring is in retaining that mate. A variety of mate retention behaviors have been documented. That is, an entire taxonomy of behaviors that are intended to prevent the defection of a mate has been developed (Buss 1988). There are a large number of mate retention behaviors but they can be classified along the broader domains of benefit-provisioning and cost-inflicting behaviors. Benefit-provisioning behaviors are designed to make the relationship more positive and decrease the likelihood of defection by bestowing gifts and affection on the partner. Conversely, cost-inflicting behaviors are designed to make defection costly to the partner through manipulation and abuse. Furthermore, these two domains differ in terms of the costs and risks faced by the individual using these mate retention behaviors. More specifically, benefit-provisioning behaviors can be seen as low risk in that they have a low likelihood of having negative consequences for the relationship, but these behaviors are also high cost in that they involve the investment of time and resources in the partner. The opposite is true of cost-inflicting behaviors. These mate retention behaviors can be considered to be high risk, but

low cost. Therefore, individuals may essentially be choosing between these two sets of tactics. A number of individual differences and situational factors may play a role in the decision between benefit-provisioning and cost-inflicting behaviors. However, self-esteem level has been demonstrated to have a profound impact on the use of mate retention behavior.

As mentioned above, self-esteem level, through the lens of sociometer theory, can be seen as an indicator of mate value (Holden et al. 2014). In turn, individuals partnered to someone of high mate value should be more motivated to retain that partner. Indeed, it has been demonstrated that individuals who are partnered with someone who is high mate value tend to engage in more mate retention behaviors (Starratt and Shackelford 2012). In other words, these individuals are motivated to hold on to this valuable reproductive resource. However, not all individuals can invest in these mate retention behaviors equally. That is, some individuals may be more prone to engage in benefit-provisioning behaviors, whereas others may be more prone to engage in cost-inflicting behaviors.

Indeed, it has been demonstrated that self-esteem level influences mate retention behavior, such that individuals who report high levels of self-esteem tend to engage in benefit-provisioning behaviors, whereas individuals who are low in self-esteem tend to engage in cost-inflicting behaviors (Holden et al. 2014). Furthermore, individuals who are held in a higher regard by their partner report less use of cost-inflicting behaviors and are perceived to engage in more benefit-provisioning behaviors (Holden et al. 2014). Put in terms of sociometer theory, this suggests that information about an individual's perceived relational value influences their decisions concerning how they manage their relationships.

Previous work has demonstrated that assortative mating occurs in humans as it does in other species. For example, individuals tend to select partners who are similar in physical attractiveness and personality characteristics as mates (e.g., Buss 1985). The mating sociometer suggests the

mechanism behind this process. Namely, the information that individuals receive through rejection influences their decisions with regard to mate selection. That is, the sociometer may function in this domain to tell individuals about their probability of obtaining particular mates. Indeed, it has been demonstrated through research using dating paradigms that rejections from potential mates are followed by a decrease in self-esteem and, in turn, a decrease in mating aspirations (i.e., selection of less-attractive mates, avoiding potential mates; Kavanagh et al. 2010). Furthermore, this mating sociometer may be differently tuned between the sexes (Bale and Archer 2013). Therefore, it appears as though the sociometer is particularly well-suited for the domain of mating and may be quite helpful in guiding the mating efforts of individuals.

Attachment Theory

Sociometer theory can also help us to better understand attachment perspectives. It has been found that attachment perspectives vary between individuals and as a result different strategies are used to regulate and detect relational value (Bowlby 1969). Also, sociometer theory and attachment theory have similar aspects (e.g., a need to belong) which support the idea that there is an interpersonal purpose for the affective and behavioral regulation system (Srivastava and Beer 2005).

Attachment theory has two dimensions which include an *avoidance* and an *anxiety* dimension. These attachment dimensions explain differences in regulatory systems of adults (Srivastava and Beer 2005). Individual differences in anxious attachment are explained by *hyperactivating strategies* which occur when a person uses extreme measures in order to receive support from others (Mikulincer and Shaver 2003). In contrast, individual differences in avoidant attachment are explained by *deactivating strategies* which are used when an individual needs to protect himself or herself from rejection and does so by avoiding others (Mikulincer and Shaver 2003). These

hyperactivating and deactivating strategies may have implications for the sensitivity or regulation of the sociometer (Mikulincer and Shaver 2003). For example, high-anxious individuals have been found to have a sensitive sociometer, whereas avoidant individuals have been found to have a sociometer that is less responsive to certain situations (e.g., Srivastava and Beer 2005).

Numerous studies have found a relationship between attachment perspectives and the sociometer (e.g., Foster et al. 2006; Srivastava and Beer 2005). For example, it has been found that perceived likability in one's social environment resulted in more positive self-evaluations, which provides support for the sociometer theory (Srivastava and Beer 2005). In addition, Foster and his colleagues (2007) found that unstable self-esteem was associated with less secure attachment, which validates the reason for the sociometer (i.e., state self-esteem fluctuates in response to acceptance and rejection). In sum, the impact that anxiety has on self-esteem shows support for a relationship between attachment perspectives and sociometer theory (Srivastava and Beer 2005).

The Extended Informational Model of Self-Esteem

Sociometer theory indicates that self-esteem has a status-tracking property which measures an individual's relational value in his or her social environment. This status-tracking property of self-esteem is an important addition to the self-esteem literature because it explains the function of self-esteem. However, the status-tracking model does not take into consideration other ways in which information is exchanged between an individual and other people in his or her social environment (Zeigler-Hill 2012). For example, the status-tracking property of self-esteem does not address how an individual's level of self-esteem may impact how he or she is perceived by another person. This is the focus of the *status-signaling* model of self-esteem (Zeigler-Hill et al. 2013) which focuses on the possibility that an individual's self-

esteem level may affect how that individual is perceived by other people in his or her social environment. For example, self-esteem may influence how one is perceived on various dimensions (e.g., romantic desirability, social dominance) such that individuals who convey high levels of self-esteem may generally be viewed more positively than those who express low self-esteem. This suggests that people may be motivated to maintain or improve their self-worth because their self-esteem may influence how they are viewed by other people (Zeigler-Hill 2012). The status-signaling model of self-esteem is believed to complement the status-tracking properties of self-esteem captured by sociometer theory and provide a more comprehensive understanding of self-esteem.

Conclusion

Sociometer theory is an important addition to self-esteem research because it provides a possible function for self-esteem. This is important because questions concerning what self-esteem actually does had largely been ignored prior to the introduction of sociometer theory (Leary 1999). There is a tremendous amount of research concerning the correlates and consequences of self-esteem, and sociometer theory is helpful for integrating much of that work by providing a clear function for self-esteem (i.e., monitoring relational value in the current social environment). Sociometer theory has been supported by numerous studies and provides an explanation for the intimate connections that have been observed between self-esteem and social acceptance. Also, sociometer theory provides a rationale as to how individuals monitor their relational value in a specific domain. However, future research should focus on important issues such as whether there is a single domain-general sociometer or several domain-specific sociometers (e.g., position in a social hierarchy; Mahadevan et al. 2016). Continued research concerning sociometer theory will help to clarify the purpose and functioning of self-esteem from an evolutionary perspective.

Definition

Self-esteem is a widely used concept in psychology and has been defined in numerous ways. Self-esteem can be described as an individual's overall sense of self-worth or personal value. It is generally accepted that self-esteem is the evaluative component of the self-concept. The self-concept is an extensive representation of the self that also includes cognitive and behavioral characteristics (Blascovich and Tomaka 1991). Within psychological research, self-esteem has been linked to a

variety of domains, from personality, clinical, and behavioral concepts to eating disorders, aggression, and criminality. Almost all psychology theory refers to self-esteem, and as such, it is widely agreed that the need to maintain and enhance self-esteem is central to human behavior (Leary et al. 1995).

Introduction

This entry focuses on three key evolutionary perspectives of self-esteem; sociometer theory, ethological perspective, and terror management theory. Each perspective will be discussed in relation to how they present the function of self-esteem and how this may contribute to an individual's manipulative communication with others.

Sociometer Theory

Many theories have difficulties when attempting to fully explain the purpose of self-esteem. Sociometer theory was offered as a new perspective, in order to help answer the questions other theories found problematic. Sociometer theory was developed by Leary et al. (1995) who proposed that self-esteem is an adaptation in the form of a gauge that monitors interactions an individual has with others. This gauge sends signals to the individual informing them as to how socially acceptable their behaviors are. According to this theory, all humans have an innate desire to have interpersonal relationships and to maintain these in a productive way. The desire for interpersonal relationships has been evolving since the beginning of the human species, as those who were part of formed groups had the highest chances of survival and, subsequently, reproduction. Individuals have evolved to have the ability to sense signals from this psychological gauge which alerts them to how much they are accepted or rejected by others and how well their overall behavior is aiding their integration into society (Anthony et al. 2007). The importance of an individual's relationship with others is often dependant on the reactions they receive from them. The sociometer is very

sensitive to even the slightest change in these perceptions, and as such, when an individual's behavior is initiating a decrease in their evaluation, the sociometer makes them aware that there is a threat to their social acceptance, which then drives them to confront the problem. According to Leary et al. (1995), there are two variations of self-esteem: state self-esteem and trait self-esteem. State self-esteem refers to the perception of changes in an individual's level of social inclusion, given a particular setting. Self-esteem increases or decreases based on positive or negative feedback. Trait self-esteem refers to an individual's accumulated lifelong perception of social inclusion and exclusion. This is sometimes considered the resting position for the sociometer as this is how an individual feels when interpersonal information is absent (Leary et al. 1995).

Sociometer theory explains much human behavior and addresses important questions concerning self-esteem (Anthony et al. 2007). A common belief is that self-esteem is to be maintained or increased; however, the sociometer theory explains that its exact function is to reduce the chances of social rejection (Leary et al. 1995). Research has suggested that low self-esteem is related to a variety of issues such as academic failure, substance abuse, depression, anxiety, and criminal behavior; however, according to Leary et al. (1995), these relationships are typically overemphasized. From the perspective of the sociometer theory, these issues are actually due to low interpersonal evaluations and sometimes social rejection. In other words, low self-esteem is not the cause of these issues, but rather, levels of self-esteem and the psychological behavioral problems co-occur. When this happens, further issues may develop and maladaptive behaviors become more common.

As sociometers monitor individuals' current standing in order to guide them toward adaptive strategic choices, it could be expected that they are designed to do this accurately. However, interestingly, there is a substantial amount of literature suggesting that most individuals have modestly inflated views of themselves and, as a result, display a variety of "positive illusions" (Taylor and Brown 1988). Krebs and Denton

(1997) explain that positive illusions to in-group and out-group biases reflect the adaptive design of these cognitive systems rather than malfunctions. In other words, sociometers may be regulated by an adaptive, built-in, positive bias. This may have implications on the behavior of individuals, specifically when interacting with others. As an individual's value or current standing in interpersonal environments is the function of how others evaluate them, the main way to increase their value could be to deceive others using manipulative communication. However, the effectiveness of impression management strategies is limited when the individual is not convinced of their levels of worth they are promoting to others, as all humans are skilled at detecting this form of deception in self-presentation (Zahavi and Zahavi 1997). "Positive illusions" may therefore denote a form of self-deception designed to increase the effectiveness of an individual's attempt to convince others to overvalue them, primarily due to their built-in positive bias or, in other words, because they believe in the level of worth they present (Kirkpatrick and Ellis 2003).

Ethological Theory

Ethology regards the adaptive value of behavior and its evolutionary history. The origins of ethology can be traced back to Darwin, the very first ethologist. His key belief was that behavioral traits are part of organisms' evolved phenotypes. During the 1960s, its application to research began; however, it has become more influential in recent years.

In relation to self-esteem, the ethological perspective proposes that it is an adaptation that has evolved in order to maintain dominance in relationships (Barkow 1980). According to this theory, human beings have evolved specific mechanisms to monitor dominance, as this is what facilitated the attainment of a mate. Favorable reactions and attention from others were associated with being dominant; thus, feelings of self-esteem became attached to social approval and respect. From this perspective, the motive an

individual has to enhance themselves positively, in evolutionary terms, is to enhance their relative dominance (Leary 1999). As this perspective deems an individual's dominance as crucially important in order to form relationships and reproduce, it's probable that humans will do anything they can to maintain this dominance. This could include using forms of manipulative communication such as telling lies, blackmailing, cheating, and seducing. More specific forms of this will be discussed in the following two short chapters, "Projected Confidence" and "Derogation of Rivals."

Terror Management Theory

Terror management theory is based on the writings of Becker (e.g., 1962) and Rank (e.g., 1941) and proposes that human beings continuously seek out ways to improve their self-esteem in order to protect them from the fear of death (Greenberg et al. 1986). According to this theory, the fear of death creates an instinct for self-preservation, just like other species. However, despite it being the same instinct, only humans are conscious that eventual death is unavoidable, and therefore, the self-preservation instinct will inevitably fail. This combination of an instinctive drive for self-preservation and the knowledge that eventual death is unavoidable can create debilitating terror (Harmon-Jones et al. 1997). The possibility of experiencing this terror is managed by a cultural anxiety buffer consisting of the cultural worldview and self-esteem. "The cultural worldview is defined as a set of beliefs about the nature of reality shared by groups of individuals that provides meaning, order, permanence, stability, and the promise of literal and/or symbolic immortality to those who live up to the standards of value set by the worldview" (Harmon-Jones et al. 1997, p. 24). Due to the cultural anxiety buffer being a social creation, humans are dependent on others to validate and maintain it. As a result, the terror management theory proposes that a large percentage of behavior, both on an individual and social level, is specifically carried out to protect the cultural worldview and self-esteem.

Similar to the other theories already discussed, within the terror management theory, self-esteem provides protection against anxiety. Therefore, the higher the self-esteem one has, the less prone they are to experience anxiety and thus display anxiety-related behaviors. For example, various studies have demonstrated that the higher the self-esteem one has, the less they are to experience death anxiety (e.g., Templer 1971). In addition, any threats which may reduce self-esteem may cause one to behave defensively in response, for example, making excuses (Mehlman and Snyder 1985) and ego-defensive attributions (Gollwitzer et al. 1982). This behavior would involve one manipulating others in order to enhance their perceived social value and, as a result, protect their anxiety buffer.

Conclusion

It is clear that the three key evolutionary perspectives of self-esteem discussed above share common themes in terms of the functions of self-esteem. Firstly, they are all concerned with protecting and preserving self-esteem. The reasoning behind this differs with each theory; however, the general principle is the same that self-esteem is important in order for individuals to live a fruitful life. Secondly, due to this importance, when their levels of self-esteem are threatened in any way, individuals will behave, sometimes undesirably, in order to protect it. As a result, various forms of manipulative communication with others can occur such as deception, telling lies, blackmail, and cheating, in order to maintain their perceived social value and self-esteem. In the next two short chapters, there will be a discussion into how individuals may manipulate others in specific ways, by “Projected Confidence” and the “Derogation of Rivals” and how specific personality constructs may accentuate this.

Definition

Self-esteem is a theory that addresses an individual's overall affective feeling of self-worth. Individuals differ both in their stable sense of self-esteem and in their self-esteem responsive to stimuli. Humans are highly motivated to increase

self-esteem and thus experience motivation to engage in similar behavior as that which previously boosted these feelings of self-worth.

Introduction

Self-esteem describes an individual's overall sense of self-worth or value based on an affective evaluation regarding the self. This evaluation encompasses both feelings about the self (e.g., "I am worthy") and emotional states, such as pride or shame. This differs from the self-concept in that one's self-concept encompasses thoughts and beliefs about the self. Self-esteem may be global (i.e., "I'm a good person"), or it may be domain specific (i.e., "I'm great at basketball"). Some individuals tend to have higher self-esteem than others on a consistent basis. This is *trait self-esteem*, as it reflects an individual's general tendency. While trait self-esteem is fairly stable across time, it is subject to short-term fluctuations based on individual experiences. For example, should something positive occur, such as receiving a promotion at work, an increase in self-esteem is likely to occur. Known as *state self-esteem*, these fluctuations influence both perception and behavior (Cihangir et al. 2010).

Rationale for Self-Esteem

Historically, approaches to self-esteem have been contradictory, arguing that it is a self-evaluation largely based on the perceived evaluations of others. Edward Higgins attempted to address this paradox through the theory of self-discrepancy. He theorized that individuals have multiple representations of the self, such as the ideal self and the actual self (1987). Self-discrepancy refers to the gap between these representations; as this gap grows, self-esteem becomes increasingly lower (Moretti and Higgins 1990). A large gap between the actual self and the ideal self is associated with low self-esteem and vice versa.

More recent work has produced two predominant explanations for the development of self-esteem in humans. Sociometer theory suggests

that humans are inherently social creatures that seek out the support and approval of others (Leary et al. 1995). As such, humans have developed a “sociometer” that allows one to detect social acceptance or rejection and translate these as increased or decreased self-esteem. The second primary theory is terror management, which argues that humans are uniquely aware among animals, of one’s impending death (Greenberg et al. 1986). To protect oneself from this paralyzing fear, humans construct beliefs, such as religion or patriotism, which provide them a sense of meaning and purpose. This sense of purpose is what one experiences as self-esteem, thereby reducing anxiety regarding one’s own mortality. Although there are conceptual variations among the current models of self-esteem, all posit that humans have an inherent drive to increase self-esteem.

We see that humans high in self-esteem tend to experience more success in life as they often approach challenges more confidently, viewing them as a way to demonstrate their abilities (Baumeister et al. 2003). Conversely, those lower in self-esteem are often simply hoping to avoid failure. Individuals high in self-esteem tend to be happier compared to people lower in self-esteem. Self-esteem is positively correlated with both life satisfaction and personal relationship satisfaction. Thus, people high in self-esteem tend to report both more stable dating relationships and more happiness within those relationships. Self-esteem is negatively correlated with a variety of mental health issues, such as depression and anxiety.

Learning, Motivation, and Behavior

Broadly, learning can be defined as the alteration of behavior resulting from individual experience. Although learning theory has advanced a great deal since the seminal works of Pavlov and Skinner, most human learning is considered associative in nature, entailing a process in which a new response becomes associated with a particular stimulus. While operant conditioning accounts for voluntary behavior, it is important to note that one need not be consciously aware of the rewards and punishments that shape one’s action (Esteves et al. 1994).

Motivation is simply our drive to do things. Thus, motivation involves goal-directed behavior, such as choosing between completing a homework assignment or napping on the couch instead. Although there are competing models of motivation, most distinguish between extrinsic motivation (doing something for an external reward) and intrinsic (doing something for an internal reward). Despite the traditional view that these two motives are at odds, more recent work has suggested that at times they may operate in tandem (Covington and Müeller 2001). This is consistent with the perspective that self-esteem fluctuations motivate behavior, as self-esteem relies on a view of the self processed through the eyes of others. Therefore, motivational drive is intrinsically linked with self-esteem. A high level of self-esteem often provides one with the motivation to take on multiple tasks. Equally important, due to the negative consequences of low self-esteem (e.g., depression), humans have strong motivation to engage in self-esteem-bolstering tasks. Fortunately, this proves effective, as humans have the capacity to learn (both consciously and nonconsciously) what behaviors result in higher levels of state self-esteem (Leary et al. 1995).

Indeed, we see that when humans experience an increase in state self-esteem driven by behavior, there is a learned response to engage in the same, or similar, behavior in the future. This has been documented for a wide range of human behavior, encompassing activities societally endorsed (e.g., athletic motivation and academic performance) as well as those in which society tends to take a harsher view (e.g., substance abuse and promiscuity). Beyond personal activities, self-esteem motivates human behavior in interpersonal settings. For example, state self-esteem predicts whether one is motivated to engage in a playful or an aggressive style of teasing others (Honeycutt and Wright 2017). Similar results have been found in such diverse domains as human interaction in online video gaming and motivation to self-disclose with others on social media. Much like a rat pressing a lever, humans will intuitively seek out the same behavior that bolstered self-esteem previously. In instances when the same opportunity is not available, such as the lack of a previous sexual partner or psychotropic chemical, humans are also

very adept at finding similar substitutes. Drug substitution is a common phenomenon encountered in therapeutic settings. Substitutive behavior is seen in a variety of domains, however, squashing the notion that it is simply the result of drug addiction. Rather, it can be likened to a self-esteem addiction, with individuals seeking other methods to achieve their self-esteem needs. Despite sounding extreme, humans have demonstrated that they are willing to forgo such pleasant activities as sex, eating, consuming alcohol, and even receiving a paycheck if they can receive a self-esteem boost instead (Bushman et al. 2011).

Conclusion

There are many sources of motivation for human behavior. Perhaps none is as powerful, though, as the need to feel a sense of personal worth. Through both conscious and nonconscious processes, humans learn what behaviors bolster self-esteem, as well as those that hamper it. In a variety of settings, humans demonstrate motivation to repeat behavior that has improved self-esteem previously. As self-esteem is crucial to an adaptive existence, humans are highly motivated to identify those actions that increase feelings of self-worth and to engage in similar behavior, even when that involves maladaptive behavior.

Self-esteem and perceived social value; Self-esteem as self-perceptions of social worth

Definition

The self-esteem system is a psychological adaptation that services the need to belong by regulating social thinking, feeling, and behavior. It functions in part by monitoring, and eventually internalizing, one's perceived value as a relational partner, both globally and in specific social domains.

Introduction

Human beings rely on their social bonds to survive and to thrive. In the early ancestral environment, a lone individual would not have fared well against predators or the natural elements. To survive and successfully reproduce, people needed to establish strong bonds with others and then work to maintain those bonds over time. Thus, natural and sexual selection shaped humans into a uniquely social species, possessing psychobiological adaptations designed to help them navigate the complexities of social interaction. Such adaptations include a powerful need to belong, which functions in part by rewarding social need fulfillment and punishing those who fail to nurture their social bonds (Baumeister and Leary 1995). For example, over and above the effects of satisfying the basic physical needs for survival, forming and maintaining high-quality social bonds brings rewards like feelings of life satisfaction, security, and general well-being, whereas failing to form such bonds results in costs like depression, intense loneliness, poor physical health, and even premature death (e.g., Cohen 2004; Uchino 2006). To service the need to belong, humans developed additional adaptations aimed at helping them to form and maintain high-quality social bonds. One such adaptation is the self-esteem system, which functions in part by monitoring, and eventually internalizing, one's perceived relational value.

Global Self-Esteem Reflects Perceived Global Relational Value

To understand how the self-esteem system services the need to belong, it is first necessary to

understand how social relationships shape the development of the self. Cooley (1902) and Mead (1934) were among the early theorists to acknowledge and document the relational nature of the self. Cooley coined the phrase “the looking glass self” to refer to the process whereby people learn to see themselves as others do. From this perspective, people's interactions with others and their perceptions of how others view the self play a significant role in shaping their sense of self and identity. For example, when a mother compliments her young daughter's artistic efforts and proudly displays her daughter's artwork on the fridge, the young girl may internalize that positive impression of her artistry, and, with time, she may come to identify as creative and artistic. As part of this broader process of self-concept development, self-esteem is also formed. Self-esteem is a core aspect of the self and reflects one's feelings of worth or value as a person. Although self-esteem is influenced by genetics and temperament (Niess et al. 2002), it is also intimately tied to the quality of one's social relationships. People infer their worth from the way they are treated by others. If they feel cared for and respected in their social relationships, they will develop the sense that they are a worthy and valued relational partner. In contrast, if they feel rejected and neglected or if they feel that others are simply unresponsive to their needs, they will develop the sense that they are not a worthy or valued relational partner. Over time, these social messages and experiences become internalized and manifest as one's sense of global self-esteem. Thus, global self-esteem is intimately twined to one's *perceived relational value*, which is one's perceived worth and value as a social partner. Indeed, some theorists have even gone so far as to propose that the two constructs are virtually synonymous.

According to sociometer theory, global self-esteem is a person's internalized sense of their perceived relational value (Leary 2004). Thus, self-esteem is proposed to be a *sociometer*, a barometer that indexes one's perceived relational value. Over time, repeated experiences of being valued by others, being treated with respect and kindness, and enjoying responsive care from loved ones create feelings of high perceived

relational value, which are then internalized into a feeling of high self-esteem. In essence, “other people value me,” becomes “I am valuable.” In contrast, repeated experiences of being devalued by others, being treated with disrespect and disregard, and experiencing unresponsive or neglectful care from loved ones create feelings of low perceived relational value, which are then internalized into a feeling of low self-esteem. In this situation, “other people do not value me,” becomes “I am not valuable.”

In turn, these self-views become an important compass for helping people to navigate their social worlds. People rely on their self-esteem to make sense of their past, present, and anticipated future social experiences. In short, higher self-esteem imbues a confidence in others’ regard and acceptance, whereas lower self-esteem does not. This confidence subsequently influences how individuals interpret their social world. For example, when people are asked to imagine interacting with a romantic partner whose negative mood has no obvious cause, lower self-esteem individuals (LSEs) and higher self-esteem individuals (HSEs) make very different attributions for their partner’s bad mood (Bellavia and Murray 2003). Because HSEs are confident about their partner’s positive regard, they are unlikely to blame themselves for their partner’s negative mood. In contrast, because LSEs are less confident about their partner’s positive regard, LSEs are more likely to feel responsible for their partners’ negative mood. Moreover, when individuals are uncertain of their likelihood of being accepted, LSEs’ social insecurity leads them to feel anxious and motivated to protect themselves from the rejection they anticipate (Stinson et al. 2009). Yet in the same ambiguous social situation, HSEs’ social confidence leads them to feel optimistic and motivated to pursue the acceptance they anticipate. In this way, self-esteem helps people make sense of, and learn from, what can often be ambiguous or confusing social experiences.

People also use their self-esteem to regulate their social behavior. For example, when they interact with a new social partner for the first time, LSEs self-protectively engage in more inhibited behaviors such as closed posture and

averted gaze, whereas HSEs promote new relationships by decreasing their use of inhibited behaviors and increasing their use of warm behaviors such as smiling and eye contact (Stinson et al. 2015). As this example attests, LSEs’ and HSEs’ social behaviors can look quite different in the same social situation. Yet the underlying motivation remains constant: People are motivated to maximize their belongingness and minimize the risk of rejection. How to go about achieving that goal will necessarily depend on one’s relational value and, relatedly, on the perceived probability of acceptance or rejection in a given situation. Because this relational calculation will be different for people of varying levels of self-esteem, people of varying levels of self-esteem will often behave quite differently in the same social situation. Thus, although LSEs may typically focus on avoiding rejection and HSEs may typically focus on achieving belonging, both types of behavior ultimately service the paramount need to belong.

In all of these examples, self-esteem is able to perform these adaptive functions specifically because it reflects people’s assessment of their relational value. But these examples have focussed on global self-esteem and global perceptions of relational value. In fact, the self-esteem system also includes *domain-specific* components that also help service the need to belong as well as other closely related social goals. That is, in addition to internalizing a global perception of their relational value, people also internalize a sense of their relational value within specific social contexts, or *domains*, resulting in domain-specific self-esteem (sometimes also called *self-evaluations*; Brown & Marshall, 2006).

Domain-Specific Self-Esteem Reflects Perceived Domain-Specific Relational Value

Social relationships are complex and varied, and so it is improbable that people possess just one psychological adaptation to help them navigate the varied social dilemmas they will face (Kirkpatrick and Ellis 2001). Romantic relationships, friendships, family relationships, and

workplace relationships each pose their own unique set of demands, and the qualities and behaviors that make one a valuable relational partner in one type of relationship are not necessarily the same qualities and behaviors that make one a valuable relational partner in another type of relationship. For example, a man's modest and sensitive nature may make him a valuable friend and confidant, but these same qualities may hinder his likelihood of advancing to a management position within a workplace that strongly values dominance in their employees (Moss-Racusin et al. 2010). Because people's skills and talents vary widely and few people are likely to possess the myriad traits necessary to succeed in every social domain, it is possible that the same person can have relatively positive social experiences in one domain, but relatively negative social experiences in another domain. Because such experiences will be internalized over time, it is also possible that the same person can have relatively high self-esteem in one domain, but relatively low self-esteem in another domain.

In turn, just as global self-esteem helps people to navigate their social relationships in general, domain-specific self-esteem helps people to navigate their social relationships within the specific, relevant domain (Kirkpatrick and Ellis 2001). So people rely on their domain-specific self-esteem to make sense of their past, present, and anticipated future social experiences in that specific domain. For example, if two women are decorated athletes on their university's swim team and have similarly high levels of athletic self-esteem, then both women will expect to succeed at the upcoming swim meet and feel optimistic and energized about the challenge of competition. However, if one has low academic self-esteem whereas the other has high academic self-esteem, they will have very different feelings and motivations about their upcoming calculus exam. People will also use their domain-specific self-esteem to regulate their behavior in that specific domain (Kirkpatrick and Ellis 2001). In general, the goal of such behavior is to meet the need to belong, but the behaviors that will best achieve that goal will vary by situation. For example, securing a stable and valued place in an organization may require

an employee to demonstrate competence and skill, whereas securing a stable and valued place in a romantic relationship may require a partner to demonstrate responsiveness and kindness. Different domains may also activate goals that are related to, but not the same as, the need to belong, including romantic and sexual goals and dominance goals, and the self-esteem system includes adaptations to facilitate the attainment of those goals as well.

Domain-specific self-esteem reflects perceived romantic and sexual value. Obtaining and maintaining high-quality romantic and sexual relationships is a fundamental part of human life and critical to the success of the human animal. Therefore, if the self-esteem system includes domain-specific adaptations, it is highly likely that one would be specialized for romantic and sexual relationships (Kirkpatrick and Ellis 2001). So it is not surprising that people do internalize their perceived value to others in these domains, forming domain-specific self-esteem concerning their attractiveness and value as an intimate partner (Messer and Harter 1986).

In turn, romantic and sexual self-esteem may also help people to successfully navigate the rocky waters of intimate relationships. For example, romantic and sexual self-esteem may facilitate adaptive relationship choices by motivating individuals to form relationships with the highest-value romantic and sexual partners that they can attain, given the limitations imposed by their own romantic and sexual value and by the norms of the "mating marketplace" (Kirkpatrick and Ellis 2001). Consistent with this account, although everyone desires to obtain the most attractive mate possible, in reality, people target their romantic overtures toward potential partners who are "in their league" when it comes to physical attractiveness (e.g., Lee et al. 2008). Such targeted pursuit is thought to simultaneously maximize the rewards that one can obtain from a partner, while also minimizing the possibility of rejection by one's love interest. Furthermore, experiencing rejection from a potential romantic or sexual partner lowers people's romantic and sexual aspirations, but leaves their friendship aspirations unchanged (Kavanagh et al. 2010), further

demonstrating the domain specificity of this adaptation.

Romantic and sexual self-esteem may also help people to calibrate their investment in ongoing relationships by monitoring both their own and their partner's relative romantic and sexual value over time. For example, because weight affects people's romantic and sexual value, and because women are expected to weigh less than men, newlywed heterosexual couples monitor their own and their partner's weight, and couples are more satisfied when wives remain thinner than their husbands over time (Meltzer et al. 2011). More generally, when one partner perceives that they have higher romantic and sexual value than their partner, they will feel less satisfied with their relationship and reduce their efforts to maintain such a relationship (Hatfield et al. 1978). So husbands who perceive that they are more attractive than their wives behave more negatively toward their wives and report lower relationship satisfaction (McNulty et al. 2008). In these ways, romantic and sexual self-esteem may function to alert an individual to inequities in their relationships and motivate responses aimed at correcting that inequity, including reducing one's investments or even ending the relationship.

Domain-specific self-esteem reflects social dominance. Another consequence of being a social animal is humans' propensity for group living and the subsequent development of status hierarchies (Anderson et al. 2015). Individuals who are ranked highly on these social hierarchies, and thus enjoy *social dominance*, receive a wide range of social benefits. For example, socially dominant individuals have greater access to resources, greater influence within their social groups, and greater success in attracting desirable mates (Sadalla et al. 1987). So once again, it is not surprising that people internalize their perceived rank on various status hierarchies, forming domain-specific self-esteem concerning their social dominance (Leary et al. 2001).

Social dominance self-esteem may also help people regulate their social behavior and, in particular, their place within the group (Barkow 1975; Kirkpatrick and Ellis 2001). For example, when people believe that they are low in social

dominance, they are more willing to accept a position of lower status within their group, whereas people who believe they are high in social dominance are less willing to accept subordinate roles (Anderson et al. 2012). Indeed, men with high dominance self-esteem report that they would react to a threat to their dominance with direct aggression, including violence (Wyckoff and Kirkpatrick 2016). In contrast, men with low dominance self-esteem report that they would respond with indirect aggression, including talking behind the offender's back. In these ways, individuals use their dominance self-esteem to guide their social decisions and behavior in an effort to optimize their inclusion and status within their social groups. Yet if an individual strives for a social rank that is higher than others believe they deserve, the group will react negatively and may even attempt to exclude that person (Anderson et al. 2006). Thus, to fulfill the higher-order need to belong or to benefit from one's actual level of dominance, people need to develop a relatively accurate understanding of their social status and dominance within their groups.

Social dominance self-esteem may also help people to negotiate dominance and status hierarchies by assessing their status relative to others and then using that information to regulate their social behavior. Although men who are high in social dominance self-esteem generally prefer to use direct aggression tactics to preserve their social status, if their rank is threatened by a higher-ranked provocateur, such men will nevertheless adapt their response and retaliate with more submissive, indirect aggression tactics (Wyckoff and Kirkpatrick 2016). Thus, people will track the relative dominance of their interaction partners and use this information to make sense of their own place in the broader status hierarchy and to guide their dominant and submissive behavior toward others.

The Attunement of Global Self-Esteem to Domain-Specific Self-Esteem

Although global self-esteem and domain-specific self-esteem are theoretically and empirically

distinguishable, they are not completely independent. This is because both types of self-esteem are internalized from the same life experiences. Perceived relational value *within* specific domains is internalized to form self-esteem that is specific to those domains, but perceived relational value *across* domains is internalized to form global self-esteem. However, the association between global and domain-specific self-esteem can vary quite widely across domains. For example, physical appearance self-esteem is very strongly related to global self-esteem, whereas friendship self-esteem is only moderately associated with global self-esteem (von Soest et al. 2016). Thus, the degree to which global self-esteem is *attuned* to domain-specific self-esteem – that is, the degree to which global self-esteem overlaps with domain-specific self-esteem – varies widely across domains (Anthony et al. 2007). But this variation is not random. A person's relational value in some domains is more consequential to their overall social value than is their relational value in other domains. Thus, a person's perceived relational value in some domains is more likely to be internalized and generalized to form global self-esteem than is their perceived relational value in other domains. As a result, global self-esteem is more attuned to specific self-esteem in some domains than to other domains.

Domain-specific self-esteem is often assessed by asking people to evaluate their possession of various skills, talents, and abilities in various domains (see Brown 2006). Therefore, the clearest way to observe the differential attunement of self-esteem to various domains is to observe the association between global self-esteem and specific self-evaluations, either for specific traits or for specific domains of traits (Anthony et al. 2007). For global self-esteem to be evolutionarily adaptive, it should be most strongly attuned to traits that are the most universally valued across social contexts, such as likeability, competence, social influence, attractiveness, and morality (Baumeister 2012). Both throughout our ancestral history and today, these traits were and are indicative of an individual's genetic fitness, ability to bear and raise offspring, and status within social groups. Sure enough, global self-

esteem is most strongly attuned to traits and qualities that are most highly prized in relational partners and less strongly attuned to traits and qualities that are less highly prized in relational partners. The attunement of self-esteem to highly valued qualities is evident in the correlation between self-esteem and specific self-views, in self-esteem differences, in self-concept clarity, and in the impact of social feedback on social decision-making (Anthony et al. 2007; Stinson et al. 2008).

Moreover, global self-esteem will attune itself to the traits that are most essential for acceptance within a particular social environment (Anthony et al. 2007). Although some traits seem to be universally valued in relational partners, the value of other traits is much more context dependent. In particular, the attunement of self-esteem to specific traits appears to depend on cultural norms and expectations. For example, for people who have an independent cultural identity (e.g., people raised in the United States or Canada), self-esteem is most strongly attuned to easy-to-observe *social commodities* like popularity, social skills, and physical attractiveness that quickly and easily distinguish among individuals (Anthony et al. 2007). In contrast, for people who have an interdependent cultural identity (e.g., people raised in Japan or Korea), self-esteem is most strongly attuned to difficult-to-assess *communal qualities* like kindness, warmth, and responsiveness that facilitate harmonious long-term relationships. Self-esteem will also attune itself to the demands of the particular social roles that people occupy. For example, in Western societies, women's social role demands that they are warm and nurturing of their social bonds, whereas men's social role demands that they cater to their individuality. Consistent with these roles, Western women's self-esteem is more strongly attuned to communal qualities than to individualistic social commodities, whereas men's self-esteem is more attuned to social commodities than to communal qualities. Such sensitive attunement of global self-esteem to cultural and social demands suggests that the self-esteem system may fine-tune itself to the requirements of the individual's specific social milieu. Ultimately, possessing such a responsive

system should benefit survival and reproductive goals by allowing individuals to effectively minimize the risk of exclusion across a variety of situations and roles.

Conclusion

The self-esteem system evolved to facilitate the acquisition and maintenance of high-quality social bonds. To fulfill these belongingness needs, the self-esteem system monitors and internalizes one's perceived relational value, forming global self-esteem. In turn, global self-esteem helps people to make sense of their past, present, and future social experiences and regulates social behavior aimed at maximizing belongingness. However, social relationships are complex and varied, and so too are people's social goals. As a result, domain-specific self-esteem also evolved to help people navigate their social relationships within specific domains, most notably, within their romantic and sexual relationships and within status hierarchies. In this way, global and domain-specific self-esteem function as a system to enable people to successfully navigate the full breadth of interpersonal relationships and social environments that they may encounter.

Self-Esteem Tracks Mate Value

Christopher Bale

University of Huddersfield, Huddersfield, UK

Synonyms

Romantic desirability; Self-worth

Definition

Self-esteem is an individual's overall evaluation of their worth. It includes both attitudinal and affective components.

Mate value refers to the desirability of an individual as a long- or short-term sexual partner, relative to intrasexual competitors.

Introduction

Sociometer theory (Leary and Baumeister 2000) proposes that self-esteem is an evolved adaptation which functions to monitor the quality and quantity of individuals' interpersonal relationships, together with their perceived desirability as a relational partner. Kirkpatrick and Ellis (2004) extended this theory, arguing that since different types of relationships present different adaptive challenges, there may be multiple sociometers, each functioning to monitor individuals' status and desirability in a specific domain. Given that successfully reproducing is a primary adaptive challenge in humans, it is likely that the sociometer system, and thus self-esteem, should be especially sensitive to assessments of individuals' sexual or romantic desirability, and accordingly, Kirkpatrick and Ellis (2004) suggest that there are specific long- and short-term mating sociometers. This perspective predicts that individuals' self-esteem should reflect both their romantic relational status and their perceived eligibility as a long- or short-term partner, which is termed their *mate value*.

Self-Esteem and Romantic Relationships

The prediction that self-esteem should be sensitive to individuals' relational status and evaluations of their romantic relationships has found empirical support. For example, in an analysis of narrative accounts of various relationship experiences, it was found that romantic rejection strongly undermines self-esteem (Baumeister et al. 1993). Similarly, individuals who have divorced experience lower self-esteem than those in intact marriages (MacDonald et al. 1987). Furthermore, individuals who report higher satisfaction with their romantic relationships (Hendrick et al. 1988), and who perceive a greater level of commitment from their current partners (Rill et al. 2009), experience higher levels of self-esteem, and men who doubt the fidelity of their spouses have lower levels of self-esteem (Shackelford 2001). Such findings suggest that self-esteem is sensitive to both individuals' relational status and their evaluations of the quality and stability of their current relationships, supporting a mating sociometer perspective on the romantic relational monitoring function of self-esteem.

Self-Perceived Mate Value

In addition to responding to individuals' assessments of their existing relationships, a mating sociometer perspective suggests that self-esteem should also reflect individuals' assessments of their eligibility for such relationships: their self-perceived mate value. A wealth of empirical evidence supports this prediction by demonstrating that individuals' self-perceptions in domains relevant to mate value predict their levels of self-esteem.

For example, Feingold (1992) conducted a meta-analysis of both published and unpublished studies which measured physical attractiveness, which forms an important component of mate value in both sexes (Buss 1989), and self-esteem. In this analysis of 38 samples, with a total of 4942 participants, Feingold found a significant

moderate positive average correlation ($r = .32$) between self-rated attractiveness and self-esteem. The analysis also found that the correlation was significantly stronger in women ($r = .32$) than in men ($r = .27$).

Historically, this sex difference in the relationship between self-perceived attractiveness and self-esteem has been explained in terms of cultural values that emphasize women's physical attractiveness over men's (e.g., Mathes and Kahn 1975). However, the mating sociometer perspective predicts that since physical attractiveness contributes more to mate value in women than in men (Buss 1989), women's self-esteem should be more strongly related to their self-perceived attractiveness than is men's.

Bale and Archer (2013) reasoned that if individuals' perceptions of their physical attractiveness influence their self-esteem because they reflect their mate value, the relationship between self-perceived attractiveness and self-esteem should be mediated by romantic self-confidence. Specifically, they argued that individuals who believe that they are highly physically attractive should have greater confidence in their ability to establish and maintain romantic relationships, and this in turn should increase their self-esteem. Bale and Archer (2013) found support for these predictions by demonstrating that in both men and women, romantic self-confidence significantly mediated relationships between a variety of measures of self-perceived facial and bodily attractiveness, and self-esteem.

In addition to research indicating that self-perceptions in domains of specific relevance to mate value, such as physical attractiveness, predict self-esteem, studies have examined relationships between global evaluations of mate value and self-esteem. For example, Brase and Guy (2004) asked participants to rate themselves on a single item measuring their overall desirability, which described a range of attributes which contribute to mate value, including physical attractiveness, social status, and intelligence. They found that participants' ratings on this item significantly and positively correlated with their self-esteem. Similarly, Penke and Dennisen (2008)

found strong significant positive correlations between a multiple-item measure of mate value and self-esteem in both men and women.

Experimental Studies

In addition to the correlational studies described above, recent experimental studies have demonstrated that manipulating participants' self-perceived mate value, and leading them to believe that they have either been accepted or rejected by potential mates, influences their self-esteem.

Pass et al. (2010) asked participants of both sexes to complete fake personality inventories and then provided them with false feedback relating to either their capacity as a romantic partner, which was designed to influence their self-perceived mate value, or their capacity as a friendship partner. Participants who received negative feedback regarding their mate value reported lower subsequent levels of self-esteem than those who had received negative feedback regarding their friendship capacity, and controls (who received no feedback). These results suggest that influencing individuals' beliefs about their desirability as romantic partners, and hence their mate value, has particularly strong effects on their self-esteem, supporting a mating sociometer perspective.

Kavanagh et al. (2010) examined the effects of perceived romantic acceptance or rejection on self-esteem in a study which was ostensibly concerned with people's perceptions of potential dating partners. Participants who indicated their relationship status as single responded to questions posed by attractive members of the opposite sex who were in fact confederates in the study. They were then provided with false feedback indicating whether these individuals would be interested in meeting up with and dating them. Participants who received positive (accepting) feedback showed increases in self-esteem compared with their pretest scores on this, and also higher levels of self-esteem than those who received negative (rejecting) feedback, who experienced decrements in self-esteem compared to their pretest scores.

These results were subsequently replicated by Kavanagh et al. (2014) who used the same experimental paradigm in a sample of men and women who were involved in ongoing romantic relationships and found similar increases or decreases in self-esteem following false mate value feedback.

Further support for the finding that inducing participants to experience either romantic acceptance or rejection influences their self-esteem was provided by a study by Zhang et al. (2015). This study involved men and women being presented with descriptions of social scenarios involving romantic acceptance or rejection, and then asked to imagine how they would feel in that situation, and recall and describe their own similar previous experiences. Participants who had been presented with romantic rejection scenarios subsequently reported lower levels of self-esteem than those who had considered accepting scenarios.

Thus, the available evidence from experimental studies supports the mating sociometer perspective by demonstrating that self-esteem is sensitive to experimentally induced manipulations of self-perceived mate value.

Other-Rated Mate Value

In comparison to studies examining relationships between self-perceived mate value and its constituents and self-esteem, there are fewer studies of how others' perceptions of attributes relevant to mate value relate to individuals' sense of self-worth, perhaps due to the relatively greater complexity of employing this method. These studies typically find much lower correlations between other-rated mate value and self-esteem than self-report studies. For example, in his meta-analysis of the literature, Feingold (1992) found only a very weak, albeit significant average correlation ($r = .06$) between other-rated physical attractiveness and self-esteem. Such findings accord with other research which suggests that in general, people are not very good at accurately appraising their own level of physical attractiveness (e.g., Santor and Walker 1999) and present a challenge for a mating sociometer perspective on self-esteem.

The sociometer system is supposed to take relevant self-evaluations of mate value as its input, and use these to produce an overall level of self-esteem, which subsequently guides adaptive relational behavior. However, if these initial self-evaluations are inaccurate, this could potentially lead to maladaptive behavioral responses, and so further research into the discrepancy between self- and other-evaluated mate value is needed to address the conditions and variables which might influence the accuracy of self-evaluations.

Conclusion

The evidence presented here supports a mating sociometer perspective by demonstrating that self-esteem relates to self-evaluations of mate value and related attributes, and is sensitive to experimental manipulations of these. However, there may be discrepancies between self- and other-rated mate value in this regard, and this warrants further investigation. Moreover, given that it is proposed that the sociometer system adaptively regulates interpersonal behavior in response to self-evaluations and self-esteem, differences in self-esteem should predict differences in the strategies individuals employ to establish and maintain mating relationships. At present, there is a lack of research which directly examines this prediction, and so future studies are needed to address this and examine whether and how self-evaluations of mate value and self-esteem influence interpersonal behavior in mating relationships.

Synonyms

Evolutionary mismatch; Relational value; Self-esteem; Social value; Sociometer hypothesis

Definition

Self-esteem is an individual's perception of self-worth, reflecting both self-evaluations and perceived evaluations from others, which may have evolved to alert and motivate individuals toward behaviors that avoid social exclusion and disapproval.

Introduction

Self-esteem is commonly understood as an individual's appraisal of self-worth as an overall judgment of the value of one's entire self or one's standing in a specific domain (Rosenberg 1965). Self-esteem is subjective, may not always tally with objective truths about the self, and is connected to what the individual considers to be

interpersonal evaluations of him or her (Leary and Baumeister 2000).

The foundations of an evolutionary perspective of self-esteem are rooted in studies that demonstrate variance in self-esteem (Twenge and Campbell 2002; Twenge and Crocker 2002), the heritability of self-esteem (Neiss et al. 2002), and the potential fitness advantages conferred by high self-esteem (Campbell and Foster 2013). Evolutionary scholars have argued that self-esteem serves an informational function in signaling how the self is evaluated by others. Such evaluations serve as a proxy for social acceptance or rejection, which then prompt behaviors aimed at improving social affiliation and increasing associated survival and reproductive benefits (Campbell and Foster 2013, p. 341). Among the various informational models of self-esteem that have been proposed in contemporary social psychology, the sociometer model stands out as one of the most important (Leary and Baumeister 2000; Leary et al. 1995).

Self-Esteem: The Sociometer Hypothesis

According to the sociometer hypothesis (Leary et al. 1995), self-esteem is regarded as an internal index of an individual's relational value to others, which is defined as “the degree to which a person regards his or her relationship with another individual as valuable or important” (Leary 2005, p. 82). Because humans evolved to live in groups and depend on the cooperation of others, relational value serves as an indicator of the likelihood of social inclusion and receiving support from others (Baumeister and Leary 1995). Thus, humans evolved to be sensitive to relational value in order to manage their inclusionary levels and avoid social expulsion or rejection (Leary 2005).

In framing self-esteem as a warning and guidance system, self-esteem departs from its traditional conceptualization as a desired end state and becomes, instead, a functional mechanism that motivates adaptive behavior based on social monitoring and self-evaluations (Hill and Buss 2006). For example, individuals detecting cues indicating social disapproval or rejection from

others, such as frowning or a decline in interest level, may experience negative feelings. This aversive state motivates compensatory behaviors aimed at restoring social acceptance and relational value, such as self-enhancement efforts (Leary 2005). Over evolutionary time, individuals who were sensitive to their relational value and managed their inclusionary status better gained an edge and outreproduced others, resulting in the sociometer mechanism being passed down the generations and establishing itself in our psychological repertoire.

Domain-Specific Sociometers

Studies have also revealed that self-esteem tracks value in specific life and social domains (von Soest et al. 2016). For example, a sports athlete's overall self-esteem may be unaffected by his academic performances because the evaluations placed on him by the sporting community, from which validation and approval are pertinent, depend more on his athletic prowess. This further demonstrates that self-esteem ultimately serves a social function – the influence of domain-specific sociometers on overall self-esteem depends on how much the relational value within these social domains matter to the self.

By extension, self-perceived mate value may also be indexed by fluctuations in self-esteem to the extent that social inclusion is linked with mate value (Brase and Guy 2004). For instance, social acceptability and popularity may contribute to an individual's mating desirability and produce a correlation between mate value and self-esteem. However, research has also found evidence for a distinction between mate value and other domains of self-esteem (Kavanagh et al. 2010). Findings reveal that although evaluations from the opposite sex affected mating aspirations and was reflected by changes in overall self-esteem, this did not generalize to effects on self-worth in terms of same-sex friendship formation. Taken together, domain-specific factors underlie self-esteem and the impact of success or failure in each domain on self-esteem depends on their significance to relational value.

Evolutionary Mismatch and Self-Esteem

In ancestral environments characterized by small population sizes and social networks with relatively few degrees of separation, any social information was likely to be self-relevant and important. Given the huge survival and reproductive costs of social rejection and expulsion, humans evolved to be highly sensitive to information that may have a bearing on the inclusionary status of both themselves and others (Lim and Yong 2019). This heightened sensitivity was likely adaptive in ancestral contexts as it enabled our predecessors to protect and manage their inclusionary status within a dynamic social environment.

Unlike the early environments that humans evolved in, modern social environments (both physical and online) present information that impacts self-esteem in far more variable and excessive ways, leading to a mismatch between the sociometer mechanism of self-esteem and the social information it evolved to process. For instance, online social networks (e.g., Facebook, Instagram, Snapchat) are laden with public displays of opinions, beautified photographs, and accomplishments accompanied by evaluations from other users (e.g., followership, likes/dislikes, shares). Modern mass media also frequently showcases idealized images of thin and fit individuals as benchmarks of beauty and mate value (Yong et al. 2017). As early humans evolved in an environment where all persons encountered were real and all social information was likely to be important, our information detection systems are not well-equipped to distinguish between virtual images of people and real persons (Yong et al. 2017) and to disregard surplus social information (Lim and Yong 2019). Therefore, perceptions of seemingly perfect individuals on social and mass media and receiving dislikes (or not receiving likes) can significantly harm our self-perceptions, as if we were in the presence of formidable individuals or had received public disapproval from others in an ancestral tribe.

When the sociometer fails to discriminate between various sources of information and processes them all as important, such overexposure to

stimulus that induces negative self-evaluations can decrease self-esteem and prompt detrimental compensatory behaviors. For instance, individuals who are exposed to attractive mating rivals online may be motivated to respond in an intrasexually competitive manner, such as by posting photographs of themselves in a sexually revealing manner to garner more likes. Extended exposure to media stimuli overrepresenting desirable mating rivals may produce an obsession with competition, leading to maladaptive self-cognitions such as body dissatisfaction and behavioral problems such as eating disorders (Yong et al. 2017). The prospect of gaining social approval via positive comments, likes, and followership may also induce hypervigilance over others' opinions, evaluations, and validation, resulting in an obsession with social media usage, dissatisfaction with the self, and heightened negative affectivity including depression (Lim and Yong 2019).

Conclusion

Research suggests that self-esteem serves an adaptive social function by helping humans detect evaluative cues that signal social standing in important life domains. This sociometer function facilitates the enactment of behaviors that increase affiliation and relational value, thereby improving survival and reproduction in ancient environments by managing the threat of social exclusion and preserving crucial social relationships. Modern social and mass media technologies, however, create a mismatch between the sociometer and the stimuli it evolved to handle. In particular, the heightened social information available today, such as the numerous idealized images of attractive individuals and social evaluations in the form of likes and followership, may overload the sociometer with negative social evaluation and undermine mental well-being. Thus, understanding the factors that trigger our evolved sociometer and how to mitigate them, such as the harmful evaluative effects of social media use, is a research area that carries both importance and urgency.

Self-Evaluations Track Perceived Mate Value

Christopher Bale
University of Huddersfield, Huddersfield, UK

Synonyms

Romantic desirability, Self-perceptions

Definition

Self-evaluations are defined as the subjective judgments individuals make about their personal qualities.

Mate value refers to the desirability of an individual as a long- or short-term sexual partner, relative to intrasexual competitors.

Introduction

Since successfully producing offspring is critical from an evolutionary point of view, men and women should be especially concerned with monitoring their status in intrasexual competition for mates (Buss and Schmitt 1993). Relative desirability as a long- or short-term sexual partner is defined as mate value, and individuals are expected to track this in order to help guide adaptive decision-making in mating contexts. Thus, individual's self-evaluations should reflect relevant social feedback regarding their mate value. Furthermore, assessments of mate value are also expected to predict self-esteem, since this is defined as a global evaluation of the self.

Social Comparison and Mate Value

Mate value is an inherently relative, zero-sum construct (Brase and Guy 2004) such that in order for some individuals to be highly desirable (have high mate value) others must be less so (have low mate value). Since mate value is defined as an individuals' desirability relative to intrasexual competitors, individuals' judgments about their mate value should be influenced by social comparisons with others.

Gutierrez et al. (1999) provided strong experimental support for the contention that social comparisons influence individuals' self-perceived mate value. They exposed men and women to images, which were either high or low in physical attractiveness, and short descriptions, which contained cues to either high or low social dominance, of individuals and asked them to subsequently rate their self-perceived attractiveness and dominance, together with their desirability as a date, sexual, and marriage partner. Women, but not men, who were exposed to highly physically attractive images subsequently rated themselves as being less desirable as marriage partners than those who were presented with unattractive images. Conversely, men, but not women, who were exposed to high-dominance descriptions subsequently rated themselves as less desirable

as marriage partners than those who had read low-dominance descriptions.

Gutierrez et al. (1999) suggested that these results can be understood from an evolutionary perspective emphasizing intrasexual competition for mates. Since physical attractiveness is a more important determinant of mate value in women, and social dominance is more important for men (Buss and Schmitt 1993), these results can be interpreted as demonstrating that individuals are sensitive to social comparisons on dimensions most relevant to their mate value and adjust their self-evaluations of their desirability according to their perceived relative standing.

Further support for this analysis was provided by a more recent study by Castro et al. (2014). These authors exposed participants to pictures and short descriptions of same-sex individuals which varied in their perceived physical attractiveness and desirability as a romantic partner. Participants who were exposed to more attractive and desirable individuals subsequently reported more negative self-evaluations, and lower overall desirability (i.e., mate value) than those exposed to less attractive and desirable individuals, suggesting that social comparisons influenced their subsequent judgments about their own personal qualities.

Self-Esteem as a Global Self-Evaluation

Self-esteem can be defined as a global self-evaluation, which includes both attitudinal and affective components. A number of correlational studies have demonstrated that self-assessments of overall mate value (Brase and Guy 2004), and its specific determinants, such as physical attractiveness (Bale and Archer 2013) and social status (Twenge and Campbell 2002), significantly predict self-esteem.

Furthermore experimental studies have demonstrated that directly influencing participants' self-perceived mate value by providing false social feedback regarding this influences their subsequent self-esteem (Kavanagh et al. 2014). Such studies support the finding that self-

esteem, as a global self-evaluation, tracks perceived mate value.

Conclusion

The prediction, derived from evolutionary theory, that individuals' self-evaluations track their perceived mate value has received empirical support from a range of experimental and correlational studies. A number of evolutionary theorists have suggested that self-evaluative systems serve to regulate relational behavior in humans (Buss and Schmitt 1993). Accordingly, studies have begun to examine how self-perceived mate value and self-evaluations influence aspects of individuals' relational behavior, such as their mating aspirations (Kavanagh et al. 2014). Future research could profitably further explore whether self-perceived mate value and self-evaluations predict other aspects of mating behavior such as mate attraction and retention tactics (Buss 1988a, b) and investment in romantic partners (Ellis 1998).

Selfish Gene, The

Spencer Mermelstein
Department of Psychological and Brain Sciences,
University of California, Santa Barbara, Santa
Barbara, CA, USA

Synonyms

[Evolution of selfishness and altruism](#); [Gene-centered theory of evolution by natural selection](#)

Definition

A seminal text in evolutionary biology that articulates the gene-centered view of evolution by natural selection, explains how self-interested genes can give rise to altruism, and introduces the meme.

Introduction

The Selfish Gene (1976) was English ethologist and evolutionary biologist Richard Dawkins's first book. Drawing on the theory developed by G. C. Williams (1966), Dawkins asserts that the gene is the primary unit of natural selection and criticizes group selection accounts. Another goal of the book was to "examine the biology of selfishness and altruism" (p. 1) by combining theories of inclusive fitness, such as kin selection, with the gene-centered view of natural selection. Dawkins also coined the meme as a unit of human cultural evolution. *The Selfish Gene*, now in its fourth edition, has remained an influential articulation of evolutionary theory and has been employed by evolutionary psychological science as a foundational theoretical perspective (e.g., Tooby and Cosmides 1992).

The Gene-Centered View of Life: Replicators and Gene Machines

Biologists since Darwin have agreed that evolution by natural selection occurs by the differential survival and reproduction of self-replicating entities. However, as explained early in *The Selfish Gene*, there has been debate as to the level(s) on which selection acts, with some advancing the possibility of selection between groups in addition to selection between individual organisms. Dawkins expresses skepticism toward group selection accounts, arguing groups lack "longevity, fecundity, and copying-fidelity" (p. 35), the key attributes of a replicator. The gene, by contrast, exemplifies those properties. Defined as a given stretch of DNA, genes are capable of persisting across generations, exist in duplicate copies found across individuals of a species, and self-replicate with a high degree of accuracy. Such attributes allow Dawkins to conclude that the gene is the "largest practical unit of natural selection" (p. 36): it is the fittest gene which outcompetes its rivals (alleles) and differentially propagates into the next generation.

All successful genes are then necessarily selfish in the sense that they seek replication at the expense of their competitors. A gene may gain an advantage over another should it code for proteins that compose what Dawkins terms survival machines, or vehicles, that enhance that gene's capacity to exploit the environment and reproduce. Early in the evolution of life, these vehicles consisted of relatively simple chemical barriers, but eventually "both animals and plants evolved into many-celled bodies" as "selection has favored genes that cooperate together" (p. 46). Central to Dawkins's thesis, therefore, is that a successful gene is "compatible with, and complementary to, the other genes with whom it has to share a long succession of bodies" (p. 84). In brief, genes are replicators that cooperate to create machines, living bodies, which enhance their individual reproduction. Selection then favors the fittest set of genes based on their phenotypic, expressed, effects on the world.

The Evolution of Altruism

Next, Dawkins references the work of W. D. Hamilton (1964) to illustrate how altruism may arise between individual organisms. Altruism is defined as a behavior which confers a fitness benefit to another at a cost to one's own fitness. For example, a honeybee may launch a suicide attack on an intruder in support of her hive mates. The selfish gene theory, Dawkins argues, best predicts such phenomena because a given gene exists as duplicates found across individuals of a species. As a consequence, selection would favor a gene that was able to promote its duplicate's fitness in another body, and "this would appear as individual altruism but it would be brought about by gene selfishness" (p. 87). Genes therefore may be selected to promote their inclusive fitness, all copies, in addition to their personal fitness, a particular copy.

This is observed in kin selection. First note that there is a comparatively higher probability that close relatives, such as bees from the same hive,

share a particular gene. Altruistic behavior may evolve should an action result in a net gain in gene replication, even at the expense of a particular individual's genes: a honeybee's costly defense of her relatives is ultimately an act that benefits the survival and reproduction of her genes across bodies. Kin-directed altruism extends into parent-offspring relations as well. Indeed, a parent can invest in its offspring at an expense to itself, but to the net benefit of the genes shared between the two (although conflict may arise between parent and child concerning the optimal distribution of investment; see Trivers (1972)).

In a later chapter of *The Selfish Gene*, Dawkins also connects the gene's-eye view of natural selection with work from economics, political science, and psychology to explain the evolution of reciprocal altruism. This is where an individual behaves altruistically toward a non-kin other, given that the roles are reversed at some point in the future. Such situations are often modeled after the prisoner's dilemma, where two agents both have the option to cooperate or defect. Typically the payout structure of the different outcomes favors the decision to defect. However, should the scenario be played out repeatedly over an indefinite period of evolutionary time, with offspring as the payoff, selection may favor the evolution of mutual cooperation. Under such conditions, simulation studies reveal that a simple "tit for tat" strategy of default cooperation coupled with punitive recrimination of defectors evolves as a stable evolutionary strategy in iterated games of prisoner's dilemma. Empirical examples that Dawkins cites include the regurgitation of blood from a successful vampire bat to a less fortunate conspecific after a hunt. Recent laboratory evidence additionally suggests humans have a host of evolved psychological mechanisms regulating reciprocal exchange relationships (Kaplan et al. 2012).

Memes: The Cultural Replicators

The Selfish Gene also devotes a chapter to human cultural transmission and evolution. Change over

time in human language and technology, Dawkins notes, exhibits parallels to genetic evolution. Indeed he writes that an evolutionary process is inevitable given the existence of any self-replicating entity. Genes are one such replicator, and in the domain of human culture Dawkins proposes the existence of a replicator he calls the meme. These are ideas or beliefs that "propagate themselves. . . by leaping from brain to brain" (p. 192) and constitute the unit of cultural evolution. Like in genetic natural selection, the meme that is most fit to its environment, in this case by appealing to human psychology, differentially reproduces across the minds of individuals. Successful memes then band together, forming clusters that mutually reinforce their transmission. Examples of such meme complexes may include religious doctrine, a symphony, or scientific theory. Dawkins's meme spawned its own field of study, memetics, whose proponents include philosopher of mind Daniel C. Dennett. Critics, however, argue that memes do not replicate from mind to mind with the requisite accuracy (e.g., Richerson and Boyd 2005).

Conclusion

Richard Dawkins's *The Selfish Gene* greatly popularized the gene-centered view of evolution and has remained influential across disciplines. In biology, Dawkins expands on several of the book's arguments in his follow-up, *The Extended Phenotype* (1982). Here, he describes how genes have consequences that extend far outside the body they inhabit, for instance, in the creation of artifacts like a bird nest or in the actions of parasites. Furthermore, *The Selfish Gene* bridged the life and behavioral sciences, foreshadowing the development of evolutionary psychological science. Specifically Dawkins provides early speculation that "our basic psychological attributes and tendencies" (p. 192) are the product of evolution, including kin selection and selection for reciprocal altruism, assertions later supported by entire literatures. Highly focused yet wide-ranging, the

selfish gene theory continues to inform research connected to the life, brain, and behavioral sciences.

Definitions and Conclusions

Consciousness research is today one of the cornerstones in neuroscience. Almost all studies in the field have focused on identifying neural events accompanying appearances in the outer world, the “qualia,” like the redness of wine. These attempts have typically neglected the issue of the “Self.” Obviously, the self and qualia are two sides of the same coin. As formulated by Ramachandran (2004, p. 96): “You cannot have free-floating sensations, with no one to experience them.” Self-awareness is the essential tool for conscious metacognition. Metacognition monitors and controls behavior, the “self,” and thereby adjusts our beliefs of the world, essential for learning by conscious experience. This occurs not only within ourselves, but, importantly, also between individuals. Self-awareness is a primordial human capacity and is of decisive importance by giving humans an upper hand in phylogenetic development of culture and society (Frith 2012).

Self-awareness, or conscious self-monitoring, is the focus of this entry, based on a recent review (Lou et al. 2016a). It was until recently considered off-limits for the natural sciences. Neurobiological research shunned the “hard question of how consciousness and self-awareness arise from a physical basis,” influenced by the philosopher David Chalmers in the late 1990s (referenced by Lou et al. 2016a). Therefore, it has been fashionable to limit the quest for understanding the workings of the brain in consciousness and self-awareness to the task of identifying neural

“correlates” of these mental functions. The limitation clearly involves the risk of arriving at two parallel worlds: a mental and a physical, without understanding how they interact. The consequence of this would be severe impediment of our understanding of the biological function of self-awareness and how it may account for disease in default.

However, using electrophysiological and pharmacological manipulations we have discovered that highly connected “hubs” of medial prefrontal and parietal are associated with self-awareness. They are not only linked to that function but indeed instrumental in its generation: Transcranial magnetic stimulation (TMS) targeting the hubs impedes specific aspects of self-awareness (Lou et al. 2004; Luber et al. 2012). Conversely, self-awareness is increased by dopaminergic challenge, primarily via GABA neurotransmission directly in the medial prefrontal cortex (Joensson et al. 2015; Lou et al. 2016b). The hubs are provided by an exceptionally rich assembly of fast-spiking parvalbumin interneurons assuring synchronization of their pyramidal cells for generation of self-awareness. The exceedingly high metabolic rate of these hubs makes them vulnerable in penuria of oxygen and/or glucose as a common final path in the pathophysiology of the many disorders with deficient self-awareness, like autism, attention deficit disorder, schizophrenia, and dementia.

Investigating Self-Awareness

Gallagher (2000), following Wittgenstein and the phenomenologists, claims that we are self-aware whenever we are conscious. Accordingly, self-awareness is an indispensable part of our experience of the world, whether it is minimal self-awareness (pre-reflective, with an automatic sense of ownership of the experience) or narrative (extended and reflective, based on retrieval of episodic (personal) memory). Minimal self-awareness may be investigated using rapidly presented stimuli, which become aware to the observer when presentation time exceeds a certain threshold (Weiskrantz et al. 1995; Kjaer et al.

2001) or by comparing first person perspective with third person perspective (Vogeley et al. 2004). Narrative (extended) self-awareness may be investigated using retrieval of episodic memory of previous judgment of self versus another person (Lou et al. 2004). Both minimal and narrative self-awareness may be ranked according to the degree of self-reference (Craig et al. 1999).

The Paralimbic Network as a Signature of Self-Awareness and Conscious Self-Monitoring

“Mind wandering,” where the person is shifting his attention to changing states and objects, is associated with shifting patterns of brain activation (Lou et al. 1999). In spite of this variability, a set of medial paralimbic regions, including medial parietal (precuneus) and medial prefrontal regions, are continuously active as measured by principal component analysis (Fig. 1) (Kjaer and Lou 2000). The network is similar to the network activated by focusing on one-self versus another person in a dark room without intended sensory stimulation or motor activity (Fig. 2) (Kjaer et al. 2002). This medial paralimbic network has proved to be a common neural signature for widely different aspects of self-awareness and conscious experiences in all functional domains examined. This was evident in a large meta-analysis of investigations using ^{15}O -H $_2$ O positron emission tomography or functional magnetic resonance imaging (fMRI) (Northoff et al. 2006).

The midline cortical “hubs” of the paralimbic network are usually linked with activity in the angular gyri, right insula, and subcortical regions (e.g., Joensson et al. 2015). The two midline hubs interact by means of recurrent oscillations in the entire frequency range measured, i.e., from less than 5 Hz to 100 Hz, with a maximum at 40 Hz. The network is active at rest without intended sensory or motor activity. That condition is characterized by a fairly large proportion of spontaneous self-referential thinking (Kjaer et al. 2002). When self-referential thinking becomes dominant, for instance, during relevant tasks in an experimental setting, a large

Self-Monitoring, Fig. 1 Cerebral activation patterns vary with shifting contents of consciousness. All conditions include a paralimbic network. The four *upper rows* represent cerebral blood flow patterns measured with ^{15}O - H_2O -positron emission tomography (PET) during yoga nidra meditation on weight of own body part (*upper row*) abstract perception of joy (*second row*) visual imagery of landscape (*third row*), and symbolic representation of self (*lower row*) (Lou et al. 1999) (a) (With permission). The

right medial parietal cortex (precuneus), prefrontal cortex, and right striatum are coactivated in all meditative states and the control state (Lou and Kjaer 2005) (b) (With permission). Visual presentation of single words long enough to be perceived consciously activates medial orbital, medial prefrontal, and medial parietal cortices when compared to subliminal presentation (c) (Kjaer et al. 2001) (With permission)

increment is seen in the entire frequency spectrum (Fig. 3) (Lou et al. 2011).

From Association to Causality

The ascription of the medial paralimbic network to self-awareness is essentially based on imaging data and can, as such, only be correlative. Accordingly, the significance of these findings for self-awareness has been disputed (e.g., Smith 2012). To test whether the paralimbic network is indeed instrumental in the generation of self-awareness, a series of intervention studies has been carried out. The investigations included behavioral consequences of electromagnetic as well as neurotransmitter manipulation of the network: Directly targeting the medial parietal and medial prefrontal region with TMS showed unequivocally that the former region is

instrumental in retrieval of self-related episodic memory (narrative self-awareness), while the latter region is instrumental in self-evaluation (Lou et al. 2004; Luber et al. 2012). The effect was simultaneous at the two disparate sites, with a latency of 160 ms after sensory stimulation (Fig. 4). This confirmed the global neuronal network hypothesis for access to consciousness and the simultaneous “ignition” of separate brain regions in the course of conscious processing (for review, see Lou et al. 2016a). Magnetoencephalography and Granger causality computation show that interaction between the prefrontal and parietal “hubs” occurs with oscillations mainly in the gamma range. Causality of lower gamma oscillations in the frontal regions for self-awareness has subsequently been confirmed by application of synchronous oscillations around

25 and 40 Hz over the frontal skull, showing stimulation induced self-reflective awareness in dreams during REM sleep (Voss et al. 2014).

Generation of gamma frequency oscillations depends on fast-spiking parvalbumin GABA-ergic interneurons. Experiments with transgenic mice deficient in these interneurons have shown

Self-Monitoring, Fig. 2 The paralimbic network in self-awareness. Retrieval of previous judgment of oneself activates dramatically the paralimbic network of medial prefrontal (anterior “hub”) and medial parietal cortices (posterior hub), together with thalamus ($^{15}\text{O}\text{-H}_2\text{O}$ PET) (Lou et al. 2004; Changeux and Lou 2011) (With permission)

deficient gamma oscillations and behavioral defects, which may be restored by optogenetically stimulating prefrontal cortical interneurons. In humans, Hall et al. (2010) found that GABA-ergic stimulation induces power increase predominantly in pyramidal cells of the prefrontal cortex. Such power increase depends on synchronization of pyramidal cell output. Recently, we have demonstrated that dopamine increases self-awareness in humans (Joensson et al. 2015) (Fig. 5) via increased GABA activity (Lou et al. 2016b) (Figs. 6 and 7). This occurs mainly in the medial prefrontal/anterior cingulate cortex, and, as a trend, in the right insula, explaining our previous finding that dopamine regulates self-awareness via medial prefrontal cortex (Fig. 5). It also explains that self-awareness is preferentially dependent on right hemisphere activity, as demonstrated by Keenan et al. by carotid infusion of anesthetics (see Lou et al. 2016a).

Also acetylcholine, an agonist of dopamine activity, may directly activate subsets of inhibitory interneurons, with synchronization of pyramidal cells as a result. This has recently been demonstrated at the cellular level in layer II/III in prefrontal cortex of mice using in vivo two-photon imaging (Koukoulis et al. 2016). Figure 8 schematically illustrates the transmitter regulation of self-awareness.

Self-Monitoring, Fig. 3 Recurrent information flow between medial prefrontal and parietal hubs. Granger causality [magnetic encephalographic (MEG) amplitudes] is seen in the entire frequency range (5–100 Hz, maximal at 40 Hz) in the prestimulus state (rest), a condition characterized by mind-wandering and self-referential thoughts (see Fig. 1). During retrieval of episodic memory (previous self-judgment), power is increased throughout the frequency spectrum (Lou et al. 2011) (With permission)

Self-Monitoring, Fig. 4 Causality of paralimbic network evidenced by transcranial magnetic stimulation (TMS). Efficiency of retrieval of self-judgment is selectively impaired at medial parietal (Lou et al. 2004) and both angular gyri, while preference for allocating positively

rated adjectives to one-self rather than best friend is selectively impaired with TMS targeting the medial prefrontal cortex (Luber et al. 2012) (With permission). The results demonstrate that the different aspects of self-awareness “ignite” access simultaneous at a latency of 160 ms

Thus neural system, cellular, electromagnetic, and transmitter physiology all testify that the paralimbic system is instrumental in self-awareness. It is tantalizing how closely this discovery, based on experimental data, fits with suggestions based on bedside clinical observations by Ramachandran (2004, p. 112).

Ontogenesis of Self-Awareness and Metacognition

The infant is probably aware only of events in the present time, while the adult capacity to put these sensations into a time perspective, with ability to

plan for the future, has to await later development (Lagercrantz and Changeux 2009). Similarly, the development of metacognition does not seem to occur until after 3 years of age.

This development occurs concomitantly with the development of resting state activity in the medial prefrontal and medial parietal hubs and insula, i.e., the paralimbic network (Fransson et al. 2011).

Pathophysiology

Due to the fundamental biological importance for the individual and society of self-awareness, self-

Self-Monitoring, Fig. 5 Dopamine increases self-awareness and gamma power. Dopamine challenge (sinemet 100 mg) decreases error rate in retrieval of previous judgment on whether adjectives fitted one-self or not compared to placebo (**a**), while retrieval of judgment of a control person is not changed significantly (**b**). (**c**) Whole brain MEG showing distribution of dopamine-induced power increase (gamma range (30–100 Hz). Preferential

power increase in prefrontal region is documented and is likely due to the distribution of dopamine receptors in the brain (Joansson et al. 2015) (With permission). The blue cross shows location of peak increase with dopamine at the MNI coordinates (0, 36, 36 mm). (**d**) Z - values > 2 (Monte Carlo simulation of the difference between placebo and dopamine medication groups)

monitoring, and metacognition, their disturbance is likely to be linked to severe pathology. Thus, frontal and medial parietal cortices are dysfunctional in a monosymptomatic condition with deficient conscious self-monitoring such as behavioral addiction (Rømer Thomsen et al. 2013) (Fig. 9). It is also the case for more complex disorders involving poor self-awareness and self-monitoring such as substance abuse, ADHD,

autism spectrum disorder, schizophrenia, and the dementias, and also traumatic brain injury. Even in a pervasive dysfunctional state such as the vegetative state, recovery of the paralimbic network is tightly linked to clinical recovery (For review see Lou et al. 2016a).

The widespread dysfunction of self-awareness in pathology is the result of the exceedingly high oxygen demand of the paralimbic default network

Self-Monitoring, Fig. 6 Dopamine activates the GABA system in paralimbic network. The distribution of the GABA receptor PET ligand [^{11}C]Ro15-4513 binding, with placebo, dopamine challenge, and placebo minus dopamine. With placebo, the ligand is bound primarily in the medial prefrontal/anterior cingulate region, and in left

and right insula. After L-dopa, the binding is reduced, seen clearly by subtraction. There is a reduction of between 5% and 20% throughout most of gray matter, indicating widespread cortical activation of the GABA-ergic interneurons. (Lou et al. 2016b) (With permission)

(Kann 2016). This makes self-awareness, conscious self-monitoring, and metacognition particularly vulnerable to deficient oxygen and glucose supply. The high metabolic requirement is mainly due to dense concentrations of interneurons in the

richly connected “hubs” of the paralimbic default network, their GABA-ergic synapses being instrumental for pyramidal cell synchronization in the paralimbic network. In particular, gamma oscillations are vulnerable to metabolic

Self-Monitoring, Fig. 7 GABA-receptor molecule at pyramidal cell membrane. Molecular model of the GABA-A receptor on pyramidal cell and of the main categories of binding sites for pharmacological agents. The GABA binds to defined subunit interfaces in the

extracellular domain (*violet region*). Activation of this molecule is the final common path for generating gamma synchrony and self-awareness (With permission). For details, see (Li et al. 2006; Nury et al. 2011; Bocquet et al. 2009; Changeux and Lou 2011)

Self-Monitoring, Fig. 8 Overview of neurotransmitter regulation of self-awareness. Fast spiking GABA-ergic interneurons are activated by dopamine and acetylcholine and quite possibly other neurotransmitters at receptors located at or near the soma. Via GABA receptors in the

pyramidal cell membrane dopamine enhances paralimbic synchrony for self-reference, a crucial constituent of any conscious experience (Changeux and Lou 2011) (With permission)

Self-Monitoring,

Fig. 9 Abnormal gamma synchronization (SI) in pathological gamblers. At rest, pathological gamblers have lower synchronization than controls in gamma band (30–100 Hz) (b vs a). (Subgroup analysis showed that this difference was present both for gamblers with and without a history of comorbid stimulant addiction (both $P < 0.05$)) (a) (Rømer Thomsen et al. 2013). This illustrates abnormal function in the paralimbic network of self-reference linked to abnormal conscious self-monitoring and metacognition in individuals susceptible to pathological gambling (With permission)

disruptions, a promising venue in the treatment and prevention of disorders of self-awareness.

Perspectives for Prevention and Treatment

The new understanding of the physiology and pathophysiology may lead to the application of novel or recently developed therapeutical strategies to increase dopaminergic activity and to improve neural interactions. These strategies may include meditation, which in independent

studies have been shown to increase dopaminergic tone and induce growth in paralimbic structure, and targeted training aiming at increasing the availability of dopaminergic receptor. Also improvement of sensory input may be an important venue to increase dopaminergic tone and induce growth in relevant structures. Likewise frontal electromagnetic stimulation of oscillations may have a role. More generally, the new discoveries provide impetus to efforts to maintain oxygen homeostasis in neural tissue ranging from decreasing oxygen demand by cooling, for instance, in distressed neonates, to controlling

cerebral perfusion pressure and autoregulation of cerebral blood flow, and obtaining optimal cerebral blood flow distribution via the capillary network (for review, see Lou et al. 2016a).

Definition

The ability to consider what is being observed about the self, the self-reflective function that allows one to marshal the resources of self-awareness to alter prediction errors. This ability provides a sense of agency in observing, planning, deciding, and evolving toward a future goal.

Introduction

Defining the self has challenged psychologists and philosophers for centuries. The phenomenon to which the word self applies derives from four domains of experience: thought, feeling, functional capacity, and the observing center. Experience in each of these realms is evidence of one's locality in space and unique psychological identity (Deikman 1982). The thinking self refers to one's engagement in controlling immediate activities and planning, such as problem solving, worrying, and imagining. The emotive self consists of affective states such as anxiety, joy, anger, and sadness, whereas the functional self is indicative of the experience of "doing." This self is aware of acting and one's capacity to affect the environment in a concrete way. The observing self is "the transparent center, that which is aware. This fourth self is most personal of all, prior to thought, feeling, and action, for it experiences all of these functions" (Deikman 1982). Self-observation refers to the active scan of these former three "selves" of inner environment and landscape.

Self-Observation as a Social Process

Humans were provided with insightful and novel means of not only expressing but also observing their own experience. This would not be possible if experience was a purely individual and private matter. Instead, we live in an inter-subjectively shared and immanently meaningful world. Humans exist as beings in constant communication with others, through which we come to develop shared perspectives on our experience.

Introspective self-consciousness is derivative of consciousness of others and not vice versa. Internal thought is a form of inner dramatization of social conduct and is thus necessarily bound up with social meanings.

Mead (1910) argued that “Other selves in a social environment logically antedate the consciousness of self which introspection analyzes.” In other words, the act of self-reflection presupposes social interaction with others. The introspection involves the incorporation of the other into the self. This conceptual move naturalizes the act of self-reflection by showing that it is an outgrowth of a social process. One’s own gesture does not initially have meaning for oneself. The gesture only has meaning for others, which is their response to the gesture. The establishment of shared meaning requires the existence of stable social institutions with interchangeable social positions – such as buying and selling. Since a vocal gesture can be heard from both sides of a social act in a social practice, it takes on a dual meaning and enables the movement from one social perspective to another. Introspective self-reflection is only possible through a history of interaction with others in social institutions.

Self-Observation and Consciousness

Self-observation results in cognizance of auto-information, such as intentions, expectations, feelings, cognitions, behaviors, and impact on others, and the ability to introspect on one’s own thoughts and to realize the relation of self to one’s social and cultural environment (Stuss and Benson 1983). It is associated with the capacities to distinguish inner from outer reality and pretend from “real” modes of functioning and intrapersonal mental and emotional processes from interpersonal communications (Fonagy and Target 1997).

This transtheoretical process involves individuals becoming aware of and learning about their own functioning in order to change maladaptive responses and generate new responses for the future (Beitman et al. 2005). In helping the individual focus attention on their own self and

idiosyncratic patterns, an external source, such as a psychotherapist, could assist in activating self-observation. This process serves as a tacit common thread woven among the different psychotherapies.

Activation of self-observation is collaboratively employed by practitioner and client within all psychotherapeutic orientations. Self-observation emerges from self-awareness, which, in turn, relies upon consciousness. Consciousness requires mobilizing functional brain structures, including the reticular activating system, and provides the platform for awareness. Awareness is the potential to be conscious of specific content such as objects, persons, and ideas. Self-awareness or “autonoetic consciousness” (Wheeler et al. 1997) is the potential to know the self and the self-in-context. Self-observation refers to actively scanning one’s inner landscape, mentalization, and the ideas in other people’s minds as well as what others think of the self (Baron-Cohen et al. 2000).

Self-Observation Within Psychotherapy

For many individuals seeking therapy, confusion, distraction, or troublesome symptoms may impede effective self-observation. Storms in the internal and external environment cloud vision, precluding accurate perception of one’s inner landscape. Although self-observation is a normal and adaptive capacity, it can be difficult to preoccupy oneself with such maladaptive thoughts, feelings, and behaviors. A safe and confiding therapeutic relationship offers a client the haven of an interpersonal relationship in which to observe the self, which is necessary to create new ideas and templates of expectations and actions to meet goals. Activation of self-observation thus empowers clients to make more informed decisions, alter prediction errors, create intentions, and plan courses of action (Pally 2004), resulting in increased freedom of choice, increased autonomy, and a wider scope of comprehension (Deikman 1982).

Conclusion

Highlighting self-observation as a core process common to all theoretical orientations simplifies

the complex dynamics of it. Although there are many techniques and interventions that may be used to activate self-observation, helping individuals become more aware and reflective of their subjective experience is a central and important theme. The recent surge of literature on mindfulness (Wylie and Simon 2004) and on the neurobiology of interpersonal learning in psychotherapy (Siegel 1999) drives the need to elucidate self-observation.

Definition

Self-reports are data that are sourced from written or verbal representation of individuals' cognitions, emotions, attitudes, experiences, behavioral intentions, and/or beliefs about the self.

Introduction

Self-reports have been widely used in evolutionary psychology research targeting many domains (e.g., mate preference, tactics of deception, cooperation, and helping). While researchers using self-reports have been able to collect and examine data that would otherwise be unobtainable (e.g., sexual fantasies), the use of self-reports in evolutionary psychology has been challenged and criticized (see Shields and Steinke 2003). Although there are valid criticisms of the self-report method, such as the potential for respondents to provide deceptive answers or to have their answers be influenced by social desirability concerns, there is strong evidence to support the use of self-

reports as a valid methodological tool in evolutionary psychology research (Allen and Yen 2001; Crocker and Algina 1986; Simpson and Campbell 2005). The following examines the uses, strengths, and criticisms of self-reports in evolutionary psychology research and offers suggestions for using self-reports in evolutionary psychology research effectively.

The Value of Self-Reports in Evolutionary Psychology

Self-reports exist in various forms, from verbal and written responses to open-ended questions, to numeric responses that indicate individuals' levels of agreement with statements that characterize a latent construct. As such, self-reports intend to measure what individuals believe to be true about themselves, their behavior, and their experiences. The greatest contribution to the literature that self-reports can make then is the obtainment of data (e.g., preferences, motivations, self-perceptions, reports of past behavior) that could not otherwise be obtained, or not as easily obtained, through other research methods. Thus, the self-report method is especially useful to evolutionary psychology research which often focuses on topics (e.g., mate preferences, violence against spouses) that, researched in any other way, could be deemed inappropriate, unethical, and/or overly intrusive.

Self-report research has been prevalent in evolutionary psychology and has in many ways provided important bases of knowledge for the field. Important, and even seminal, research using self-reports has tested evolutionary hypotheses pertaining to human mate preferences (e.g., Buss 1989), mate retention (e.g., Buss 1988), mating desires (e.g., Regan and Dreyer 1999), tactics of deception (e.g., Tooke and Camire 1991), violence against spouses (e.g., Buss and Shackelford 1997), strategies for elevating your status within a social hierarchy (e.g., Cummins 2005), familial helping (e.g., Burnstein et al. 1994), and many other relevant and important evolutionary

psychology research topics (see Buss 2015 for a comprehensive review). This research employing self-report measures has been heavily cited, creating important foundations for testing further evolutionary psychology hypotheses to expand the understanding of human cognition and behavior.

One of the major strengths of self-report research is that it is a time- and cost-effective method for doing research, reducing the necessary expenses in time, money, and labor to conduct. Self-reports often do not come with the drawbacks of other research methods that may be more expensive, laborious, and obtrusive (e.g., studies employing behavioral observations of individual participants). When beginning a new research program or exploring a new research question, it may be unwise to choose other, more arduous research methods because these efforts may be unfruitful and the invested resources (e.g., time, money) may then be wasted. Thus, self-reports are a practical methodological tool and a sensible first step in a research program.

One particular strength is the predictive power of self-report measures. Self-reported emotions and beliefs have been shown to predict important attitudes and behavior in testing hypotheses derived from evolutionary psychology. For example, using a sociofunctional theory of intergroup prejudice, researchers have used self-reported perceptions of the specific threats posed by different groups to predict specific emotional profiles evoked by these groups (Cottrell and Neuberg 2005), thus demonstrating that there may be many different functionally relevant kinds of prejudices as opposed to one generalized prejudice. Similarly, researchers have used self-report measures to test hypotheses about the adaptive functions of disgust sensitivity and their relationship to fundamental moral values (e.g., van Leeuwen et al. 2016) and voting behavior (Inbar et al. 2012). As another example, self-reports have also been successfully used to predict cost-inflicting mate retention behaviors. Men's partner-directed insults were found to be related to women's reports of their partners' mate value, such that women's decreased

assessments of their male partners' mate value were associated with more frequent insults from their partners (Miner et al. 2009a, b). These are but a few prominent examples of the value of self-report measures in conducting research in evolutionary psychology.

An additional benefit of self-report methods is that they can be designed to measure opinions or preferences that allude even the participants' own conscious knowledge, for instance, when the participants may not be aware of, or able to explain, how the variables at play influence their perceptions and behaviors. For example, male participants may not be able to articulate, or even be consciously aware of, their preferences for female romantic partners as a function of the women's waist-to-hip ratio (WHR). However, by systematically manipulating the size of a woman's figure using line drawings, Singh (1993) was able to conclude that women's distribution of body fat (i.e., WHR) played a critical role in men's judgment of females as healthy and attractive. Similarly, if asking participants whether or not they prefer unique or average faces, participants are likely to mistakenly report they prefer unique faces. This may at first appear to be a limitation of the self-report method. However, by designing self-report methods in which participants can rate their preferences for faces that are manipulated or chosen based on key features, such as their representing a composite "average" face of varying numbers of individual faces (e.g., Grammer and Thornhill 1994; Jones 1996), researchers can gather important data about individuals' preferences, even when the factors that influence these preferences may be outside of the participants' own conscious awareness.

Self-reports have thus far played an important role in building the foundation of many psychological fields, including the field of evolutionary psychology. Innovative researchers have used creative methods in which to test their hypotheses and make significant contributions to the knowledge bases of their fields. It should be noted that the above strengths are in no way an exhaustive list of the strengths of self-report methods; however, these strengths do provide evidence that self-reports are a versatile methodological tool that

researchers may adapt to fit their needs in the pursuit of important research objectives.

Criticisms and Limitations of Self-Report Methods

The uses of self-reports, particularly with college student populations, have been criticized and challenged in the literature (see Shields and Steinke 2003; Silvers 2011). One particular limitation noted among these criticisms is that participants may be deceptive when reporting their attitudes, preferences, and behaviors. This criticism is not necessarily specific to evolutionary psychology, but the topics examined in evolutionary psychology research may make this a particularly important concern. Evolutionary psychology often examines sensitive topics (e.g., extramarital affairs, unusual sexual fantasies), and thus participants may be especially hesitant to report thoughts or experiences they fear will result in negative judgment by others. Alternatively, participants may not be reporting the information “truthfully” because they have limited self-knowledge or because they themselves have been deceived by their own lies (Paulhus 1988). Thus, the issues of self- or other-focused deception are particularly worrying limitations of the self-report method.

Another criticism leveled at self-report methods is that they are a fallible source of data because seemingly insignificant variations in the wording, format, or content of the items or questions to which participants respond may have significant unintended effects on how participants respond (Schwarz 1999). To illustrate this point, the self-report research that has examined individuals’ responses to infidelity has yielded contradictory results. Early work found sex differences that supported the *jealousy as a specific innate module* (JSIM) hypotheses through hypothetical forced choice self-reports (Buss et al. 1992). However, alternative methods, such as using rating scales or self-reports of individuals’ actual experiences, revealed evidence that was contrary to the JSIM (see Harris 2003 for a comprehensive review). Again, while this is not a concern unique to

research conducted only in evolutionary psychology, it is a concern that evolutionary psychology researchers must consider when employing self-report measures.

Perhaps the biggest limitation that self-reports must overcome is that self-report measures are not direct or exact records of an individual’s actual behavior. As such, because self-report data are dependent on individuals’ perceptions and interpretations of events, collected data may be subject to bias. Further, various cultural norms or stereotypes may taint the data. And because human memory is fallible and often unreliable, researchers must be careful when asking questions that pertain to the past frequency of behaviors or to the recollection of past experiences.

As discussed above, data collected by self-report measures may also be unreliable due to participants’ desire to be viewed as favorable. For instance, participants may knowingly report their preferences dishonestly or be motivated to exaggerate their experiences (e.g., embellished accounts of sexual experiences), especially when they believe that their responses may be publically evaluated. Social desirability concerns (Crowne and Marlowe 1960; Paulhus 1988) have long been a problem in self-report data. Researchers must be aware of this issue and take reasonable steps to reduce their participants’ desires to respond to self-report measures in ways that enhance their own social impressions, such as by ensuring the anonymity and confidentiality of the participants’ responses.

Addressing the Limitations of Self-Report Methods

While the criticisms of self-reports discussed above are valid, it is important to remember that all research methods are imperfect. All research methods bring with them some degree of measurement error in their failure to completely and accurately assess the constructs they operationally define. Researchers must be cognizant of the limitations of the research methods they employ and make informed decisions about designs and procedures. Further, although it may be impossible to

eliminate measurement error, researchers may implement methods that reduce it. A preferable method for the reduction of measurement error in self-reports is triangulation (Buss 2015; Kenrick and Keefe 1992). By pairing self-reports with a multi-method, multi-measure approach, researchers can obtain more robust and ideally converging results, providing them with more confidence in their conclusions.

Because seemingly trivial variations in the wording or format of self-report materials can strongly influence participants' answers (Schwarz 1999), researchers should take particular care in wording their self-report measures. Making sure that the participants' understanding of the items or questions match what the researchers intend is crucial to the interpretation of their results. Thus, researchers are encouraged to pilot test their materials (see Schwarz and Sudman 1996) to assess their reliability and validity before large amounts of data are collected.

Finally, with new technological advances, researchers can collect large amounts of data while eliminating various sources of measurement error (Miller 2012). For example, to help reduce problems associated with memory or lack of self-knowledge, researchers may employ text messaging as a method in order to receive immediate, or near-immediate, data that do not rely on the individual to recall past events or count the frequency of past behaviors. Furthermore, with the now ubiquitous use of smartphones, researchers can create interactive surveys and experiments to collect data from real-world behaviors, experiences, and emotions in real time, rather than later in a lab room (Miller 2012).

Conclusion

All research methods have strengths and limitations. When designing studies, researchers should be aware of the particular, potential limitations of each research method and take the necessary steps in reducing measurement error and avoiding unnecessary pitfalls. The criticisms associated

with self-report measures are real; however, researchers aware of these criticisms may still use self-report methods in their research to obtain reliable and valid results. In the absence of infinite resources, self-reports are valuable, practical, and cost-effective measurement tools that can be employed by researchers in their investigations of fascinating research questions in evolutionary psychology.

Definition

According to self-categorization theory (Turner et al. 1987), self-perception is influenced by salient self-categories, and the ascription of ingroup-defining characteristics to the self is defined as self-stereotyping.

Introduction

Self-categorization theory (Turner et al. 1987) posits that group-level processes occur through the process of categorizing or cognitively grouping the self as either similar to or distinct from another class of stimuli. One can categorize the self on a *personal* level, as a unique individual, different from other individuals (based on idiosyncratic attributes), or conversely, categorization can be done on a *social* level, in terms of identification with social groups, which would render

one's cognition to be filtered through a salient social identity. The operation of self-concept on a personal or social level is thought to be dependent on the perceiver's contextually driven frame of reference and the subsequent categories that may become salient (Turner et al. 1987; Oakes 1987).

Self-categorization theory explains that social identity emerges by way of *depersonalization*, whereby the self is perceived less as a distinct idiosyncratic individual and more as an interchangeable member of a social group. It is through awareness of ingroup norm or prototype that ingroup assimilation and the sense of interchangeability can occur, as prototypes serve to describe and prescribe group appropriate ways to think, feel, and behave, thereby establishing normative behavior among members. Group-based self-construal, and in general intragroup processes, is fostered through the process of *self-stereotyping*, which involves ascribing ingroup-defining traits to the self, and in doing so enhancing the similarity between self and ingroup members, while augmenting the contrast between the ingroup self and outgroup members. The objective of this entry is to discuss self-stereotyping when sex is a salient category (i.e., me, as a woman, versus you, as a man), while deliberating on how gender-based self-stereotyping can be understood from an evolutionary perspective.

Self-Stereotyping by Sex

Group identification entails the incorporation of an external social category into internal self-definition, thereby transforming self-perception and behavior to become consistent with ingroup stereotypic characteristics and norms. Self-categorization can be based on a novel, never-before encountered social category, such as arbitrarily assigned group, or a preexisting one, such as sex (or gender). In instances when sex category becomes primed or salient, *general knowledge about gender stereotypes may become activated*, which may momentarily shape an individual's self-concept based on the sex-category membership they identify with. This leads to gender-based

self-stereotyping. For example, simply put, if an individual woman categorizes herself as a woman in contrast to a man, through her sex-based social category identification ("us women"), her self-perception and behavior will become depersonalized to accentuate her similarities to other women, and attenuate her idiosyncratic personal differences from other women, thereby enhancing perceptually her stereotypical difference from men (Hogg and Turner 1987).

As Hogg and Turner (1987) explained, it is important to note that while social stereotypes are *shared* representations of the defining features of a particular social category, they are nonetheless still cognitively represented by individuals, who possess their own individual idiosyncrasies shaped by personal experiences; in other words, the social stereotype can be thought of as superimposed on the individual stereotype, and for that reason social stereotypes, while shared, are not necessarily rigidly invariant across individuals. With that said, the individual idiosyncratic self-concept will be significantly overshadowed by the similarities embedded in the social, shared self-concept, leading to stereotypical behavior among members of an ingroup (Hogg and Turner 1987).

Evolutionary Reasoning on Own-Sex/Gender Self-Stereotyping

It is well known that there are different beliefs about the characteristics associated with women and men. These differential attributes are the basis for gender-based categories that distinguish the male social group from the female group. When sex category becomes salient, identification with a gender/sex category engenders alignment of self-perception and behavior to match one's own-sex group, leading to stereotypic behavior that ultimately highlights one's similarity to the prototype of their gender ingroup, while simultaneously augmenting stereotypical differences from the gender-outgroup. It is conceivable to link the content of gender-based stereotypes to adaptive traits that have been favored through sexual selection, and to also conceive of engagement in gender-

based stereotypic behavior (self-stereotyping) as a way of propagating evolved mating strategies. As it will be elaborated on, the different sex or reproductive roles of men and women point to differential adaptive challenges in the context of reproduction and mating. The different adaptive problems may have engendered differences in the psychologies of men and women that contribute to gender stereotypes, and the engagement in gender-based stereotypical behavior may serve as a means for easily identifying whether a particular individual is a man or a woman in order to facilitate sexual selection. Gender-based self-stereotyping can therefore be thought of as a form of secondary sexual characteristic that taps into our evolved mating preferences and strategies.

Sexual selection refers to the processes associated with any aspects of breeding behavior, such as competition with members of the same sex and species over mates, as well as the process of mate selection (Darwin 1871). The dynamics associated with sexual selection are thought to be influenced by the degree to which each sex focuses their reproductive effort on parenting or on mating (for a review, see Geary 2002). For a woman, a 9-month pregnancy is the minimum obligatory investment to produce a child, whereas for a man, one act of sexual intercourse is the minimum investment required to produce that same child. Given a woman's larger parental investment (e.g., nine months gestation, post-birth nurturing via lactation and breastfeeding), they are predicted to desire certain characteristics in men that would lead to an increase in reproductive success. A woman's sexual selection is predicted to include competition for men who are willing and able to make the most parental investment – such as willingness and ability to invest economically in raising their offspring and high social standing or dominance, which are typically correlated with resource acquisition – in order to ensure that the offspring reaches reproductive age; while for men who do parentally invest, mate selection criteria includes health, fertility, and sexual fidelity (Davies and Shackelford 2008), which are cues linked to probability of either immediate or future reproductive potential.

Women, cross-culturally, place a greater importance on good financial prospects of a marriage partner than do men and value qualities linked to resource acquisition, such as ambition, industriousness, and social status (for a review, see Buss 2007); similarly, female American undergraduate students were found to prefer, far more than men, mates who show ambition and industriousness, which are qualities linked to securing higher salaries and occupational status (for a review, see Davies and Shackelford 2008). Women's greater preference for mates who are able to economically invest in their offspring may have produced sexual selection pressure for men to have an evolved psychology that motivates meeting these preferences (Shackelford and Davies 2008). Indeed, this may have been the case, as women's universal mate selection criteria resemble the characteristics found in male-specific gender stereotypes, which include attributes such as strong, controlling, assertive, and achievement-oriented (for a review, see Burgess and Borgida 1999). Interestingly, previous studies of the behavioral tactics that men use to attract or retain mates have demonstrated that “men tend to display and bestow resources on the women they are trying to attract and retain. They tend to denigrate their rivals by impugning the rival's professional prospects, such as mentioning that the rival is lazy, lacks ambition, or lacks clear goals in life” (for a review, see Buss 2007). Men's engagement in tactics that involve displaying their own resources, ambitiousness, and physical and social dominance can be conceived of as a demonstration of men's engagement in sex-based self-stereotyping that has roots in evolutionarily adaptive sexual selection endeavors.

Cross-culturally, men place a greater importance on a marriage partner's physical attractiveness than do women, by showing preference for cues to youth and physical appearance (e.g., full lips, smooth and clear skin, lustrous hair, and low ratio of hips to waist). These cues are valued, as they have previously been shown to have a robust link to a woman's health and fertility, and serve as strong predictive factors in either immediate or future reproductive success. Men's greater

preference placed on physical attractiveness is hypothesized to have resulted in women evolving a psychology that motivates them to use strategies that facilitates meeting this preference (Davies and Shackelford 2008). Women are indeed found to have success with tactics involving appearance enhancement more so than men, and behavioral strategies used by females to attract or retain mates include not only putting more effort into appearance enhancement but derogating rival's by pointing out their physical flaws (for a review, see Buss 2007). With respect to parental investment, the greatest threat to the reproductive success of a man is being cuckolded into raising children and directing economic investment toward children that are not genetically related to him. This may have led to men having evolved a psychology that causes them to prefer women who are not sexually promiscuous and are likely to be sexually faithful to them. Cross-culturally, men do place a greater importance on the chastity or virginity of a potential marriage partner (for a review, see Buss 2007), and indeed females have been shown to have success with mating tactics that involve displaying their own sexual fidelity and impugning rivals as being sexually promiscuous (for a review, see Davies and Shackelford 2008). Other female stereotypical traits include attributes such as being warm, caring, deferential, and interpersonally skilled (for a review, see Burgess and Borgida 1999), which are agreeable and nurturing traits that have been adaptive due to promoting the survival of their children. Thus, gender-specific self-stereotyping may reflect the inherited strategies that our ancestors have relied on as they faced many different sex-specific adaptive problems in the context of reproduction and mating. Gender-based self-stereotyping may therefore serve as behavioral signals of an individual's ability to successfully fulfill their respective sex roles based on strategies that maximize reproductive success.

Conclusion

Reproductive success, or the passing of genes to the next generation, involves not only producing

offspring but also ensuring that at least some of these offspring survive to reproductive maturity. Two different sexual strategies can accomplish this: one is the "quality" strategy which consists of heavily investing in a few offspring to increase their individual chances of reaching reproductive maturity, and the other is a "quantity" strategy, which consists of producing as many offspring as possible, in the hope that some will survive to adulthood (Cunningham and Russell 2004). Based on the aforementioned parental investment theory (Trivers 1972), evolutionary psychologists have argued that the "quantity" strategy would primarily benefit men, whereas the "quality" strategy would benefit women. The differing reproductive roles and beneficial strategies (quantity versus quality) may have created divergent selection pressures for each sex, paving the way for the evolution of differential secondary sexual characteristics to meet sex-specific challenges. Examples of these secondary sexual characteristics are competition and aggression among males over limited fertile females, or nurturing qualities that would promote child bearing and care in females. These evolved traits and behaviors are attributes that parallel the content of gender stereotypes, and may therefore reflect characteristics that have been selected and inherited based on the sexual selection pressures expressed by preferred mates. Exhibiting gender-specific characteristics that are valued by a potential mate through gender-based self-stereotyping may be an inherited strategy that facilitates sexual and reproductive success via expressing increased potential in these domains.

Gender-stereotypes could be conceived of as sex-specific attributes that have enhanced the mating strategy and success of our ancestor, and self-stereotyping, when gender is salient, may be a way of behaviorally displaying evolved features that signal a promise for reproductive success.

[r strategy](#)

Definition

A reproductive strategy characterized by a single reproductive episode over the course of a lifetime.

Introduction

The term *semelparity* refers to a reproductive strategy characterized by a single reproductive episode over the course of a lifetime and contrasts with *iteroparity* (see ► [“Iteroparity”](#)). Semelparous species have only one reproductive episode in a lifetime; thus they invest all reproductive efforts into optimizing one reproductive episode (e.g., by having a single litter with several offspring; Ricklefs and Miller 1999), at the expense of losing future mating opportunities. This risk, however, pays off to some species. Previous research and theoretical models have shown that semelparous species have higher expected adult mortality; thus it is more optimal for semelparous species to invest all resources into

a single reproductive episode (e.g., Young 1990). Nonetheless, both reproductive strategies are observed in plants and animals. Semelparity is uncommon in vertebrates – exceptions include a few fish (e.g., bony fish, Osteichthyes), lizards (e.g., Labord's chameleon, *Furcifer labordi*), amphibians (e.g., gladiator frog, *Hypsiboas rosenbergi*), and a few mammals (e.g., marsupials) (e.g., Braithwaite and Lee 1979). Among invertebrates, most cephalopods and some insects (e.g., butterflies, arachnids) present a semelparous reproductive strategy (e.g., Schneider and Lubin 1997; Fritz et al. 1982). Most annual plants reproduce a single time during their life span, thus are considered semelparous species (Young 1990).

The Evolution of Semelparity

The evolution of semelparity (and iteroparity) has been subject of several theoretical models. One set of models attempts to explain the differential evolution of semelparity by examining the trade-offs between reproductive effort involved in offspring produced and offspring forgone (for a review, see Roff 1993). According to the trade-off models, the reproductive effort of an organism occurs optimally when the benefits of offspring produced outweigh the costs of offspring forgone. That is, the greatest distance states the optimal reproductive strategy for a given species. Semelparous (vs. iteroparous) species usually have higher expected adult mortality (e.g., Schneider and Lubin 1997). Accordingly, for species with high forgone offspring rate (i.e., high mortality rates), the optimal reproductive strategy is to invest all reproductive efforts into a single reproductive episode in a lifetime.

In a classic paper, Cole (1954) proposed a demographic model for the evolution of semelparous and iteroparous reproductive strategies. Cole's model resulted in a semelparous species that has one litter of four and dies afterward having the same rate of population growth than a iteroparous species bearing annual litters of an average of three offspring. This suggested that an advantage of just one offspring would select for semelparity. Charnov and Schaffer (1973) then identified that sensible

variances in adult and infantile mortality were responsible for costs of a semelparous reproductive strategy that were not accounted by Cole's model. These demographic models have been successful when tested with real-world systems. That is, according to these models, the risks involved in semelparity pay off to species in which the benefits of devoting reproductive efforts to a single reproductive episode outweigh the costs of losing future mating opportunities.

Semelparity and K-Selection

Semelparity should not to be confused with a *K*-selection strategy. The former regards to a reproductive strategy in which a single reproductive episode occurs in a lifetime (vs. multiple reproductive episodes; see ► “Iteroparity”), and the latter refers to selected traits that cause a species to have fewer but higher-quality offspring (compared to a *r*-selection strategy; see Pianka 1970). For example, the North Atlantic right whale (*Eubalaena glacialis*) has limited offspring, costly gestation, and high parental investment (Knowlton et al. 1994). Despite the high costs of bearing an offspring, this particular type of whale can still produce more than one offspring in a lifetime. Therefore, it cannot be considered a semelparous species, even though it clearly follows a *K*-selection strategy.

Conclusion

Semelparous species incur in a single reproductive episode over the course of a lifetime (Cole 1954). Numerous semelparous species produce more than one offspring in a single litter (Young 1990). Optimal reproductive strategies differ between species within species, and the semelparity reproductive strategy played a key role in the evolution of several species' reproduction and parenting systems (Roff 1993).

Semen

► Seminal Plasma

Semen and Vaginal Chemistry

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Definition

Seminal fluid possesses more than just a transport medium for spermatozoa. Seminal fluid also contains dozens of compounds, including ovulatory- and pregnancy-related hormones. Many of these compounds can also be absorbed through the vaginal wall.

Introduction

Semen is a reproductive fluid. Seminal fluid has been selected over generations to be composed in such a way that it not only houses sperm but also increases probability of conception and pregnancy maintenance (coagulates to retain sperm in the vagina, decreases acidity for sperm survival, etc.). This has a direct effect on the fitness of the human male.

Ney (1986) suggested that the high concentrations of estrone and estradiol, testosterone, dihydrotestosterone, follicle stimulating hormone and luteinizing hormone, prolactin, and 13 different prostaglandins in semen could be biologically active if absorbed by the vagina. Researchers have administered many of these hormonal compounds through the vagina and determined high levels of absorption that elevated blood levels for hours after administration (Schiff et al. 1977; Villanueva et al. 1981).

What is in seminal fluid? Glucocorticoids that aid in the stress response and reaction to pain, androgens that increase sexual desire, endogenous opiates that increase pain relief and pleasure, immunomodulators which increase sperm longevity and appear to have significant effects on the launching of pregnancy, and myotonia enhancing compounds that aid in orgasm. Seminal fluid also contains a host of ovulatory compounds (including estrogens, luteinizing hormone, luteinizing hormone releasing hormone, and follicle stimulating hormone) and over a dozen compounds that aid in the initiation and maintenance of pregnancy. Beyond these, there are also several affiliative and psychotropic hormones and neurotransmitters (see Burch and Gallup 2006 for review).

The major question when faced with these findings is why: why do humans have such elaborate and unique seminal fluid? The answer lies in the evolutionary history of human females. Women are concealed ovulators. Males cannot synchronize insemination with ovulation if they cannot detect ovulatory signals. The chief male strategy then becomes surveillance and support of the female along with consistent coitus, ensuring paternity. In fact, Sillén-Tullberg and Moller (1993) found that this shift from ovulatory signals to concealed

ovulation emerged and then triggered a shift in the human mating system, pushing humans to become monogamous. This placed a significant pressure on males, forcing them to choose between monogamy (with its paternal certainty) and promiscuity (with its high reproductive pay off). Males that could, through semen chemistry, better synchronize insemination with ovulation would have a reproductive advantage. Research has shown that other parameters of ejaculate (volume and sperm counts, for example) vary with context of ejaculation (masturbatory/coital) and are greater during coitus. It is possible the same is true for seminal compounds.

Strategies such as this have been found in other species, with “ovulation induction factors” found in several species, and in many, this factor is a potent stimulator of luteinizing hormone (Adams and Ratto 2013). Human males have five times more luteinizing hormone in their semen than circulating blood levels (and also Luteinizing hormone releasing hormone) and researchers have long argued that coitus-induced ovulation occurs in humans as well (Jöchle 1973). If concealed ovulation led to ovulation induction strategies in humans, how does seminal fluid compare in other primates who do not possess concealed ovulation? Chimpanzees, our closest living primate relatives, are conspicuous ovulators. If the composition of human semen has evolved to compensate for the loss of ovulatory signals, then levels of luteinizing hormone and follicle stimulating hormone should differ between human and chimpanzee semen. Levels of luteinizing hormone were lower (and more variable) in chimp than human semen and follicle stimulating hormone was completely absent (Burch and Gallup 2006).

The effect of seminal compounds on female physiology does not end there. The triggering of ovulation does not guarantee conception, and conception does not guarantee pregnancy. Human seminal fluid also contains a host of pregnancy inducing and maintaining compounds that actually assist the zygote in implantation and the formation of the pregnancy (Relaxin; Human Chorionic Gonadotropin; Human Placental Lactogen; Pregnancy-Specific β 1-Glycoprotein; Placental proteins 5, 12, and 14; and Pregnancy-associated

plasma protein). Several fertility studies have shown that seminal fluid exposure effects positive outcomes. Live birth rates in couples undergoing In Vitro Fertilization are significantly improved when women engage in intercourse circa embryo transfer (Bellinge et al. 1986; Tremellen et al. 2000). Treating women who suffer recurrent miscarriages with seminal plasma pessaries improves pregnancy success (Coulam and Stern 1993). Preeclampsia studies show a cumulative benefit of semen exposure over time: limited sex or condom use is linked with increased risk (Klonoff-Cohen et al. 1989; Robillard et al. 1995) and the effect is partner-specific (Dekker et al. 1998).

Some of these effects might also be result of a variety of cytokines and growth factors that culminate in improved endometrial receptivity to the implanting embryo. Cytokines have embryotrophic properties and also contribute directly to the optimal development of the early embryo (Robertson 2005). Cytokines and male alloantigens in seminal fluid are sufficient to induce a state of “active immune tolerance” to paternal alloantigen and this priming positively influences fetal survival in later gestation (Robertson et al. 2009).

Perhaps the most fascinating (or at least the most publicized) effect of seminal fluid is that on female psychological functioning. Seminal fluid contains a variety of neurotransmitters and mood regulators; Tyrosine, DOPA, Norepinephrine, Serotonin, Melatonin, and Thyrotropin-Releasing-Hormone. Very little research has been done on the effects of these compounds on the female psyche.

Gallup et al. (2002) reported that females who engaged in intercourse but never used condoms showed significantly lower scores on the Beck Depression Inventory than those who used condoms more frequently and those who never engaged in intercourse. Depression scores between females who used condoms and those who did not engage in intercourse were not significantly different. In then “no condom” and “little condom use” groups, time since last sexual intercourse and depressive symptoms were positively correlated. Being in a relationship, length of that relationship, use of oral contraceptives, and frequency of sex did not affect depressive symptoms.

Conclusion

In short, human semen biochemistry appears to have been selected to suppress the female immune system and increase female sexual interest, bonding, the potential for orgasm, the probability of conception and pregnancy maintenance, partially in response to concealed ovulation. This process also appears to have the byproduct of affecting female physiological and psychological functioning.

Semen Displacement

- Physiological Evidence for Human Sperm Competition

Semen Familiarity

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Definition

The effect of one man's semen on the physiological state of a female and patterns of reproduction related to a consistent partner's seminal fluid versus a new partner's.

Introduction

It has already been established that seminal fluid contains several compounds that may assist in

pregnancy maintenance and prevent spontaneous abortion (see [Cross-References](#) below). Roberts and Lowe (1975) estimated that about 78% of all human conceptions do not make it full term, so spontaneous abortion is a major factor in human reproduction.

Some researchers have determined that semen familiarity, repeated exposure to the father's semen, may be a factor in pregnancy maintenance. Live birth rates in couples undergoing in vitro fertilization are significantly improved when women engage in intercourse circa embryo transfer (Tremellen et al. 2000). Treating women who suffer recurrent miscarriages with seminal plasma pessaries improves pregnancy success (Coulam and Stern 1993), and preeclampsia studies show a cumulative benefit of semen exposure over time: limited sex or condom use is linked with increased risk (Klonoff-Cohen et al. 1989). This "cumulative benefit" also implies that this exposure is to seminal fluid of the same male.

Preeclampsia, a cluster of symptoms (including high blood pressure and protein release), is a contributing factor to maternal mortality in the USA and a major cause of perinatal morbidity and mortality (Einarsson et al. 2003; Klonoff-Cohen et al. 1989). One of the major protective factors against preeclampsia appears to be repeated exposure to the father's semen. Women who have limited exposure to the father's semen are at increased risk for preeclampsia (Robertson et al. 2003). Preeclampsia also is more likely in pregnancies that occur by artificial insemination, a procedure that sometimes requires the separation of spermatozoa from the seminal fluid (Koelman et al. 2000).

Because the likelihood of preeclampsia is higher for women who are not cohabitating with the child's father, for women who conceive as a result of artificial insemination, for women who use condoms, and for successive pregnancies that involve a change in paternity, there may be biochemical differences that distinguish one man's semen from another's. Dekker et al. (1998) identified changes in "paternity," the female's sexual partner, as a predictor in preeclampsia. This implies that it is not only exposure to semen that aids in pregnancy maintenance but the consistent

exposure to the father's semen. Although not all of the factors that distinguish one male's seminal fluid from another's have been identified, Doss and Louca (1991) showed that the ratio between testosterone and dihydrotestosterone is different from one man to another due to the heterogeneity of seminal plasma. They hypothesized that this ratio may be useful in identifying a particular man's semen.

Conclusion

Davis and Gallup (2006) argue that the absence of semen familiarity may be a cue that triggers female mechanisms that evolved to terminate pregnancies that were not in a woman's reproductive best interests. Making a judicious mate choice and being in a committed relationship with the child's father are two markers of reproductive success for women. Not only do females have a vested interest in the other 50% of the genes being carried by each of their children in ancestral environments the chances of her children surviving to reproductive age would have depended on the presence of a committed, protective, and provisioning mate.

Semen from In-Pair Partner

Ray Garza

The Oklahoma Center for Evolutionary Analysis (OCEAN), Oklahoma State University, Stillwater, OK, USA

Synonyms

In-pair copulation; Sperm competition

Definition

Semen from in-pair partner describes the psychological and adaptive functions of semen during copulation between individuals in a relationship.

Introduction

Aside from its main role in aiding fertilization, semen production can be influenced by psychological, physical, and social factors that promote its quantity and quality in sexual behaviors. These influences play an adaptive role in increasing the probability that fertilization may occur and aid in reducing the probability of another man fertilizing the ova of their partner. For instance, men have cognitive mechanisms that are sensitive to specific contexts that may doubt their paternity, and this may influence their sexual behavior with their current partner. Additionally, there is evidence to suggest that semen has psychological and biological effects, such as reducing emotional distress (Gallup et al. 2002) and reducing prenatal complications (Koelman et al. 2000). Semen from in-pair partner provides an insight on how human relationships are affected by the perception of infidelity and on the interdependent relationship between copulation and psychological health. Taken together, semen from in-pair partners may suggest the important role of long-term pair bonds where ingestion of semen ejaculate would be most common.

Sperm Competition

Sperm competition is when females engage in sexual intercourse with different men which results in sperm from different partners occupying the reproductive tract (Parker 1970). Although this implies an act of infidelity in a relationship, the thought of unfaithfulness in a relationship can cause changes in semen production and sexual behavior. A man who is at risk of his partner engaging in extra-pair sex may end up investing resources in offspring that are not genetically related (Pham and Shackelford 2015). This may result in psychological and physical changes in a relationship to counter that risk, such as increased semen production, or methods to remove a possible partner's semen, known as semen displacement. There is a body of research that has looked into time spent away from a current partner and the effects it has on semen quantity in men. Time

spent away from a partner puts a man at risk for cuckoldry, as there is no certainty that his partner has been faithful. When away from their partner, men ejaculate more and produce more sperm until their next copulation (Baker and Bellis 1993). This suggests a strategy of sperm competition as an attempt to counter the possibility of another man's semen in the female's reproductive tract.

Another tactic that men incorporate when perceiving that their partner have been unfaithful is semen displacement. Semen displacement refers to sexual intercourse where there is deep thrusting to remove semen from a rival male. This can be accomplished by long copulation, where there is more time to remove semen from intercourse, or by quickly ejaculating following an assumption of infidelity. If this strategy is to be effective, then it should be used in situations where there is a likelihood of partner infidelity or where there has been an amount of time of separation where extra-pair copulation may have occurred. In situations where women have male coworkers or male friends that they spend time with, men have reported more semen displacing behaviors, such as increased and deep thrusting (Barbaro et al. 2015). Deep thrusting may be an effective strategy if copulation with another male has been short, where the rival male's semen is still in the vagina. However, if time between an extra-pair copulation and in-pair copulation has been longer, a shorter copulation with an in-pair partner may be more effective as displacement would not be effective once sperm has entered the reproductive tract and away from the vagina (Barbaro et al. 2015). Semen displacement behaviors are also prevalent in committed relationships (e.g., marriage). It has been reported that men engage in semen displacing behaviors at their next copulation with their partner if their wives spend more time with male friends or male coworkers (Pham et al. 2017). This suggests that sperm competition is not independent of relationship status, but dependent on psychological and environmental factors where one is at risk of cuckoldry.

Perceptions of infidelity may be mediated by mate guarding behaviors. Mate guarding is a costly behavior, but it is effective if it can ascertain faithfulness and paternity certainty. However, this may be determined by the quality of the male that is

utilizing mate guarding, such as his level of attractiveness and dominance. It has been found that men who engage in more mate guarding behaviors display lower quality of ejaculate and less quality of sperm than men who engage in less mate guarding behaviors (Leivers et al. 2014). It could be argued that this may be influenced by mate value, where high quality males may not engage in mate guarding behaviors because their high quality traits prevent women from leaving them. Men of low mate value may engage in more mate guarding behaviors because they are at greater risk of their partners leaving them (Leivers et al. 2014).

Psychological Effects of Semen

It has been suggested that semen can have psychological effects when absorbed through the vaginal wall due to the many hormones in the seminal plasma, such as testosterone, prolactin, follicular stimulating hormone, estrogen, and luteinizing hormone (Gallup et al. 2002). Known as Ney's hypothesis, the effects that seminal plasma has on female behavior is through the modulating effects that prostaglandins have on neurotransmitters. Estrogen can have mood-elevating properties in postmenopausal women and younger women who take estrogen-based contraceptives (Gallup et al. 2002). If semen does have psychological effects, then women who have intercourse without condoms, where semen would be in the reproductive tract, should report less emotional distress, such as depression. Research investigating the role of semen and emotional distress has shown that women who have sex without condoms have fewer depressive symptoms compared to women who use condoms and women who abstain from sexual intercourse. Although it can be argued that this association may be due to sexual frequency, women who have frequent sex with condoms report similar depressive symptoms to women who abstain from sexual intercourse. These effects also carry over to lower suicide attempts in women who do not use condoms when compared to women who use condoms and women who abstain from sexual activity (Gallup et al. 2002).

Preeclampsia Risk and Semen Ingestion

There are many other functions that semen may provide an in-pair partner, whether it is semen obtained through oral or vaginal sex. Although there are many different reasons why couples engage in oral sex (i.e., arousal, pleasure, rival detection), the benefits of fellatio on women has not been fully explored. There seems to be an important role that semen plays in couples who are expecting children, which may highlight a function of oral sex where it is dependent that the female swallows the semen. In women who are pregnant, preeclampsia is a complication that results in hypertension and can lead to severe consequences in pregnancy. Research has shown semen may be beneficial in women who are at risk for preeclampsia (Koelman et al. 2000). Prior to gestation, semen has been found to induce immunological responses in women who ingest their partner's semen through oral sex resulting in a reduce likelihood of preeclampsia. This is through the result of molecules in semen that aid in inducing immunological tolerance in women.

Are the benefits of semen ingestion dependent on relationship context? Research has investigated if these effects can be explained by women who receive semen through their own partner (in-pair) or semen received through an out-pair, such as donor sperm. There are many reasons why women would want to receive donor sperm, such as issues related to infertility, or lesbian couples who are trying to conceive. In looking at the risk of preeclampsia, it has been shown that women who receive semen from a donor are at a significant increase from developing preeclampsia compared to receiving semen from their partner (Gonzalez-Comadran et al. 2014). Although the findings are unclear as to why donor semen would increase preeclampsia, it points to the important role that relationship context may have on semen ingestion in developing preeclampsia.

Conclusion

Semen serves as an important vehicle for transporting sperm in an attempt to fertilize an ova.

This process can be modulated by environmental and psychological factors where a male may feel compromised as to his certainty in paternity. This discrepancy may influence the amount of semen produced, as well as the behaviors utilized to combat the possibility of a rival's sperm inside the reproductive tract of a partner, as is seen in semen displacement. Although sperm competition has received a lot of attention in the literature, semen's influential role to mental health and prenatal care is equally important. It is noteworthy to point that these influences may be the result of relationship context, where semen ingestion may be dependent upon semen obtained from a committed relationship (in-pair partner).

[Semen-based cost of mating](#); [Toxic molecules in seminal fluid](#)

Definition

In some taxa, molecules in the ejaculate can lower the longevity of females that receive them.

Introduction

Mating requires cooperation between the sexes. In species in which there are separate sexes, females and males of the same species must communicate to find each other, and sperm and eggs need to be united in the correct manner to achieve fertilization. And, at least in some organisms with parental care, cooperation between parents continues after the progeny are produced. Yet, against this background of cooperation, there are less salutary interactions. For example, in some taxa, males transfer in their seminal fluid molecules that result in premature death of their mates (e.g., in the fruit fly *Drosophila melanogaster*, nematode worm *Caenorhabditis elegans*, bean beetle *Callosobruchus maculatus*, Colorado potato beetle *Leptinotarsa decemlineata* (see Chapman et al. 1995; Shi and Murphy 2014 for examples)) or interfere with the function of other males' sperm (a point that even merited mention in an episode of the TV series *House*). How and why would this occur?

Males and Females Have Different Reproductive Strategies

Males and females have a shared reproductive interest in passing on their genetic material to as many high-quality offspring as possible. But strategies to best achieve this may often differ between the sexes (e.g., see Chapman et al. 2003 for review). Egg production requires a large energetic investment that may outweigh investment in sperm or seminal fluids. In some organisms, progeny care and feeding are also disproportionately performed by females, requiring additional energy expenditure. Thus, it is often advantageous to females to mate selectively and use the sperm from the highest-quality males to fertilize their gametes. Phenomena such as limiting the extent of multiple mating, or increasing pair-bonding, may be useful strategies in this regard. Males, in contrast, may often benefit from adopting a very different strategy. With gametes that are energetically cheap to produce and can be made in very large numbers, males can benefit from mating multiply and frequently, with less regard to mate quality – it is a numbers game. When males are abundant, this can manifest as polyandry (more than one male mating with a given female), provided that this is not diluted by male social dominance strategies. When more than one male has mated with a female there is competition among the males' sperm/ejaculates for fertilization opportunities. In a competitive situation such as this, any modification that can increase a male's access to fertilization opportunities will increase his reproductive success and that of his male descendants who display it. Thus, over evolutionary time strategies such as increased sperm numbers and faster, "better," sperm may be selected for.

Seminal Proteins Are Critical Contributors to Reproductive Success

A very important contributor to male reproductive success is the set of molecules that males make and transfer (along with sperm) to females during

mating. These molecules include seminal proteins, whose effects can promote the success of their “own” sperm by harming the sperm of rival males. This was demonstrated in Hymenoptera (bees and ants; den Boer et al. 2010) in which sperm viability is decreased when sperm are incubated in seminal fluid of a different male (relative to within their own seminal fluid).

Seminal proteins also affect females in important, reproduction-enhancing ways, in all animals thus far examined (e.g., Avila et al. 2011 for insects). Within the female, seminal proteins access and act upon the neuroendocrine and reproductive systems, resulting in physiological changes that impact the female’s reproductive efficiency. For example, beta-NGF in the seminal fluid triggers female camelids to ovulate (Ratto et al. 2012), and an unrelated seminal protein, ovulin (Rubinstein and Wolfner 2013), does so in *Drosophila melanogaster* fruit flies. These actions ensure that eggs are quickly available to be fertilized by the male’s sperm, an outcome that is advantageous to the reproductive success of both the male and the female.

Differences in Reproductive Strategies Impact Seminal Protein Evolution

It is thought that seminal fluid proteins may have been selected initially in order to coordinate the many complex reproductive processes that need to be initiated following mating. Hence, seminal fluid proteins allow the matching of the timing of the cascade of reproductive changes in females that must occur in order to achieve successful fertilization. Such effects would be mutually beneficial for both sexes. For example, the female could “use” the male’s provision of seminal fluid to regulate her physiology to increase energy-demanding egg production only after mating has occurred and thus not “waste” energy on producing and ovulating eggs that cannot be fertilized and will die.

However, once there was the opportunity for males to influence the reproductive investment of

females, particularly in polyandrous species, the stage was set for males to potentially “manipulate” female physiology and benefit male fertility or competitive success even if exacting costs in females. The different optimal reproductive strategies for males and females means that seminal proteins can be selected for that are advantageous to males, even if their effects might not benefit females. For example, seminal fluid of insect males contains molecules that decrease their mates’ propensity to remate (Avila et al. 2011). This effect can increase a male’s relative reproductive success by decreasing the likelihood that his sperm will be usurped by a rival’s or that his progeny will be in competition with half siblings from subsequent reproductive episodes by the same mother. Although this remating inhibition can potentially provide some benefit to the female (giving her more time to lay eggs and avoiding any negative physical consequences of mating itself), this effect of seminal proteins also decreases the female’s likelihood of mating with a “better” second male. In this sense, the interests of males and females are in conflict, with the seminal protein benefitting the male to the potential detriment of the female.

As long as a strategy benefits a male relative to his rivals, it can be selected for even if it causes harm to the female. If the negative effects of a seminal protein are large enough, female resistance can evolve, for example, by selection for mutations that make receptors for the seminal protein less abundant or less active or by increasing the amount or activity of seminal-protein degrading enzymes. This in turn can favor the emergence of new mechanisms in males to circumvent resistance, such as alternative strategies to prevent remating. An interesting example in this regard is the *Drosophila* “sex peptide” seminal protein. One function of this peptide is to decrease the female’s propensity to remate (Chen et al. 1988). Decreased remating propensity is most effective for the male if it persists as long as his sperm are available in the female to fertilize eggs. Interestingly, the sex peptide becomes attached to sperm, which maintains it in the

female as long as sperm are present while protecting it from degradation by proteases in her circulatory system. Kubli and colleagues suggest that the development of sperm binding as a way to retain and protect sex peptide in the female may have led to the evolution of very long *Drosophila* sperm: males can retain more sex peptide in females this way. A number of studies have provided evidence for such an “arms race” of evolution of molecules and strategies by males, followed by counter-evolution of the females to resist harm, leading to new male strategies.

Semen Toxicity Occurs in Some Taxa and Likely Relates to the Sexes’ Differing Reproductive Strategies

A striking example of a situation in which males benefit at a clear cost to females is that seminal proteins decrease the longevity of females in some taxa (e.g., Chapman et al. 1995; Shi and Murphy 2014). Some decrease in female longevity as a cost of mating seems unsurprising. The energetic cost of producing eggs and progeny can trade off against somatic maintenance and health. However, if such earlier death is balanced by the benefits of having more progeny, especially early in life, then there is no overall net fitness cost. In order to attribute costs of mating to the receipt of seminal fluids, it is therefore important to consider the net outcomes of lifespan versus reproductive success. For example, when the source of the cost of mating (Fowler and Partridge 1989) was probed genetically in *Drosophila melanogaster*, it was found that there were additional costs besides increased egg production. In particular, a component of seminal fluid caused premature death of the female (Chapman et al. 1995). In experiments in which egg production and male exposure/harassment levels were controlled, females that mated repeatedly with males that supplied seminal proteins died sooner than females that had mated with males that did not supply seminal proteins. Thus, a seminal protein(s) decreased female longevity. Subsequent experiments showed that a particular seminal protein, the *Drosophila*-specific sex peptide, caused decreased female

longevity (Wigby and Chapman 2005), although overexpression assays suggested that several other seminal proteins might also have a negative effect on female lifespan.

How and why can a seminal protein, like the sex peptide, result in significant harm to females? The reasons are as yet unknown but we can make some guesses. One possibility is that the sex peptide’s negative effects on female lifespan could be an “intended” and directly selected function that is actively selected for. Such an explanation would suggest that it is advantageous to the male to cause his mate to die soon after mating, either so that she would rapidly produce progeny as a terminal investment or so that her death would decrease the chances of her producing subsequent offspring with a rival. Although this is a formal possibility, there is as yet no experimental support for it.

An alternative hypothesis is that the female’s longevity decrease is not a direct consequence of the effect of sex peptide but is instead a side effect of some other, beneficial, effect. In this model, there would have been selection for the effects of sex peptide and the female response system to be tuned to balance the fertility-enhancing benefits of the male peptide with females being sufficiently resistant to its negative effects on longevity so as to have minimal impact on net fitness. Consistent with this interpretation, the effects of mating on female longevity in *Drosophila* are small – multiple matings are needed before a statistically significant longevity decrease is observed – and the increase in female death rate occurs after at least the initial burst of progeny production is completed. At the moment, we do not know which of the sex peptide’s many effects could result in this indirect but negative effect on female longevity, but there are several possibilities. First, the sex peptide increases feeding by females. Increased feeding is also required to provide increased nutrition to meet the energy expenditure of egg production. However, since increased caloric intake is also associated with decreased longevity in many organisms including *Drosophila*, feeding stimulation by sex peptide could have negative consequences on longevity. A second possibility is that sex peptide also decreases siesta sleep in mated females, improving their chance of finding egg-laying sites but also perhaps resulting in

increased energy expenditure that could lead to earlier death. The sex peptide also induces immune gene expression in females, and it is possible, but is not yet demonstrated, that a high level of immune-gene expression could reduce female viability either due to increased energy expenditure on immune proteins or perhaps due to deleterious effects on the female's microbiome. Finally, sex peptide changes hormone levels (juvenile hormone) in mated females; the shift in hormonal milieu could potentially be costly. In all cases, the positive effects of sex peptide on reproduction would have outweighed these negative side effects.

Although costs of semen receipt have been reported in a number of invertebrate taxa (e.g., Chapman et al. 1995; Shi and Murphy 2014) (it has not been searched for systematically in vertebrates), this phenomenon is not universal and is even context dependent in some taxa. Moreover, the one well-characterized inducer of early death in mated females – the sex peptide (Wigby and Chapman 2005) – is not found outside the genus *Drosophila*. And, not all *Drosophila* species show post-mating longevity decreases. For example, polyandry is reported as beneficial to female lifespan in *D. simulans* and in *D. mojavensis* increased mating confers resistance to desiccation stress. Hence different molecules and mechanisms may underlie costs observed in different taxa. This is consistent with our argument above that semen toxicity is not a directly selected effect. Rather, we suggest that in some taxa, a male-benefitting effect of a seminal protein may exact costs in females. Counterselection will keep the level of cost expressed in those taxa at a level that does not unduly impact upon net fitness, though some cost may be expressed as a pleiotropic effect of the beneficial reproductive effects of the seminal protein. Consistent with this, the toxicity of proteins that cause costs, and potentially even the type of toxicity they cause, are not expected to be conserved.

Conclusion

Semen toxicity represents a fascinating reflection of the fact that males and females use different

strategies for optimal reproductive success. It will be intriguing to examine what has led to the evolution, and retention, of semen toxicity in some taxa but not in others.

Semicircular Canals

Michael Khalil
University of Nicosia, Nicosia, Cyprus

Synonyms

Inner ear structure

Definition

The superior, posterior, and lateral semicircular canals of the inner ear responsible for balance and the movement of the head

Introduction

The semicircular canals are part of the structures of the inner ear, specifically the bony labyrinth. (Munir and Clarke 2013). The canals are filled with perilymph (Hain and Helminsky 2007). Their neurosensory elements are known as the crista and cupula, and the neurosensory elements of the canals' otolithic organs are known as the macule and the striole. The semicircular canals are responsible for keeping the person's balance and posture; they are also responsible for the movement of the head with the help of the otolithic organs.

Structure of Semicircular Canals

The semicircular canals are part of the bony labyrinth of the inner ear (Munir and Clarke 2013). The bony labyrinth consists not only of the semicircular canals but of the cochlea as well. The canals are filled with a fluid similar

to the cerebral fluid, called the perilymph (Hain and Helminsky 2007), which is contained in the perilymphatic duct in the subarachnoid space (Chang and Khana 2013). There is perilymph also between the membranous and the bony labyrinth (Pickles 2012).

Each semicircular canal is perpendicular to the other canals on the ipsilateral side and coplanar with the contralateral canals (Chandrasekhar 2013). Each canal forms two thirds of a circle with a diameter of roughly 6.5 mm and a cross-sectional diameter of 0.4 mm (Lee et al. 2016). The neurosensory elements of each canal are called the crista and cupula and are perpendicular to the plane of the canal (Chandrasekhar 2013). Each otolithic organ has a curvilinear shape at right angles with each other. Their neurosensory elements are called the macule and the striola; the macule is located around a central dividing line, and the hair cells of the striola are located either toward the line in the utricle or away in the saccule (Chandrasekhar 2013).

Function

The three semicircular canals of the inner ear (superior, posterior, and lateral) perceive the turning motion of the head (Munir and Clarke 2013). They are oriented at right angles to each other. Each canal is responsive to angular motion and is paired with a canal on the contralateral side so that what is an excitatory stimulus to the one, to be inhibitory to the other (Lee et al. 2016).

Otoliths

The utricle and saccule respond to the pull of gravity rather than the motion. These two otoliths provide mass to the balance system hair cells, and when the head is moved into new positions, gravity pulls on that mass and pressures the tips of the hair cells. Consequently, this sends a nerve signal to the brain which indicates movement (Munir and Clarke 2013). A structure called semicircular ducts has the same structure as the bony semicircular canals where they are contained

(Chang and Khana 2013). They compose the kinetic labyrinth that senses the acceleration or rotation of the head. The semicircular ducts are attached to the utricle, and at the end of each duct there is a structure called the ampulla, which contains the sensory neuroepithelium on the crista ampullaris. This is covered by the cupula; a gelatinous substance entrenched with hair cells (Chang and Khana 2013). The cupula is displaced by the endolymph motion based on the rotational acceleration of the head, which bends the hair cells in the opposite direction of the rotation, subsequently opening the ion channels and depolarization of the hair cells, which in turn increases the firing of its afferent fibers (Chang and Khana 2013). Rotational deceleration of the movement of the head displaces the cupula in the same direction of the head movement, which subsequently closes the ion channels of the hair cell which causes it to become hyperpolarized, having the result of a reduction in afferent nerve firing (Chang and Khana 2013).

Conclusion

The structure and function of the semicircular canals were reviewed as well as a brief discussion of how the otolithic organs contribute to keep a person's posture and balance in check was provided.

[Ejaculate](#); [Semen](#); [Seminal fluid](#)

Definition

Human male reproductive fluid, separate from spermatozoa (sperm)

Introduction

Only 5 % of an ejaculation consists of sperm. The remaining 95 % is called “seminal plasma” which consists of a bewildering array of different ingredients, including various hormones, neurotransmitters, endogenous opiates, and immunosuppressants. Burch and Gallup (2006) have theorized that many of the different components in seminal plasma may have evolved to commandeer the female reproductive system in

such way as to promote the reproductive best interests of males (Burch and Gallup 2006; Gallup and Burch 2006; Gallup et al. 2012).

Compounds in Seminal Plasma

Just as there appear to be context-specific mechanisms that promote sperm competition by adjusting the number of sperm in the ejaculate to take into account the probability of rival male sperm in the female reproductive tract, Burch and Gallup have championed the view that similar mechanisms operating at the level of the testicles may modify or adjust the composition of seminal plasma to fit the particular situation or setting in which ejaculation occurs. Gallup et al. (2012) refer to this as the “Topping off Hypothesis.”

For example, although it may appear counter-intuitive, the chance of conception as a consequence of nonconsensual sex or rape is 2–6 times higher than is true for consensual sex (see Gallup et al. 2012 for a review). Contained in human seminal plasma are several compounds necessary for female reproduction, including follicle stimulating hormone (FSH) and luteinizing hormone (LH). During the ovulatory phase of the menstrual cycle, changes in FSH and LH serve to prompt the maturation and release of an egg. Researchers have theorized that during sexual assault, evolved mechanisms may operate to adjust the levels of these hormones in seminal plasma to increase the likelihood of induced ovulation and conception as a consequence. At least in principle, this hypothesis could be easily tested by assaying semen from victims of sexual assault or by collecting and assaying semen from sperm donors who watch either consensual or non-consensual pornography while masturbating.

Conclusion

It is entirely possible that evolved mechanisms may exist that also function to adjust different aspects of the chemistry of seminal plasma to fit other reproductive contexts as well (Gallup et al. 2012).

Semiotic Constraints

Donald Favareau

National University of Singapore, Singapore,
Singapore

Definition

Semiotic constraints refer to the notion that the behavior of animals (including humans) is organized at least in part by what the things that they encounter in the world signify, or “mean,” to them. In the context of evolutionary psychology, such “meanings” do not refer to self-conscious mental processes but to naturally evolved patterns of behavior wherein a given stimulus has come to indicate, or point to, something other than itself for the members of a species. The term “semiotic constraints” has thus been used to refer both to those signs in the environment that productively constrain, and thus give shape to, an organism’s behavior, as well as to the conditions under which such stimuli have become meaningful for an organism to begin with.

Introduction

“Semiosis” comes from the Greek terms *sēma* “sign” and *-ōsis* (“process”). Biosemiotics is thus the study of sign-processes in living systems, and “semiotic constraints,” in this context, refer to the evolutionary and material constraints that shape those sign processes and that, in turn, shape the behavior of organisms in response to them.

The Danish molecular biologist and biosemiotician Jesper Hoffmeyer explains the need for this concept well, when he notes that “every organism is tossed at birth into a [world of] sounds, smells, movements, colours, shapes, electrical fields, thermal radiation, waves of all kinds, chemical signals, touching, and so on . . . to which it must adapt correctly, if it is to survive” (1996: vii).

The question from the evolutionary biologists’ point of view, then, is: What are the processes by which any given naturally occurring phenomenon – the vibrations in the air made by the setting down of a paw in the forest, for example – can come to reorganize organisms’ biology evolutionarily such that an appropriate stimulus-response is reliably produced in the presence of this “sign” of danger (e.g., a twig snapping) that is not dangerous in itself? And even more fundamentally: By what evolutionary processes have the intrinsically nonmeaningful aspects of the natural world – air vibrations, light wavelengths, molecular structure, etc. – become the meaning-laden sights, sounds, smells, and colors of living creature’s phenomenal experience?

Semiotic Constraints on the Population Level

Twentieth-century physiologist and experimental biologist Jakob von Uexküll (1864–1944) coined the term *Umwelt* to refer to the perceptual surround specific to each species as a result of its own particular biological constitution. The wavelengths of light that constitute the colors of the human world do not all appear in the *umwelt* of bats, just as the ultrasonic sounds by which bats

navigate the world are undetectable to humans. Biology thus constrains which “signs” of the external world each species can detect, and thus act upon, in order to accomplish its survival needs of hunting, fleeing, mating, etc.

Within this semiotic niche, the detections and responses of other animals – particularly a species’ conspecifics, predators, and prey – to such signals exert evolutionary selection pressure, such that the evolved capabilities of one species result in the evolved counter-capabilities of another (e.g., the tiger moth’s evolved ability to “jam” the sonar that the bat has evolved to detect the tiger moth). The differential success and failure of such signal-using strategies and behaviors for a population, too, form part of the ever-present semiotic constraints shaping animal evolution.

Semiotic Constraints on the Biological Level

For physicist and systems scientist Howard Pattee (1926–), the notion of “biological information” can best be thought of as those material constraints upon a living system’s *internal dynamics* that have been selected over evolutionary time in order to preserve and enhance an organism’s survival. Building upon mathematician John von Neumann (1903–1957) pioneering work on self-reproducing automata, or systems that contain within them the encoded instructions for copying and maintaining themselves, Pattee (1972, 1997) distinguishes between the laws governing the physical dynamics of a living system, which are universal and time-reversible, and the informational control mechanisms acting upon those dynamics, which are species-specific and the product of each species’ history of natural selection.

The same molecule, for example, can and will trigger different processes to take place in different organisms (and even in different parts of the same organism). “What makes a molecule a message (i.e., endows it with the power of physically harnessing the dynamics [of a living system]),” writes Pattee’s biographer Joanna Rączaszek-Leonardi, “is not its particular physical or

chemical properties, but its evolutionary history within a system: i.e., its being selected for bringing about a particular phenotypic effect" (2012).

Such dynamics-controlling mechanisms are informational, or semiotic, in two senses: (1) they are "constraints that, while obeying laws [governing all physical structures], can also implement arbitrary syntactic and formal rules" specific to the cohesive functioning of each species' particular bodily organization, and (2) they have, again, become organized as such as a result of a species' history of successful and unsuccessful interactions with the world via the recursive feedback processes of natural selection.

Semiotic relationships are understood above as involving processes that are broader than, and evolutionarily prior to, the much later evolution of human language and meaning, for here "semiotics" denotes "the study of how meaning is built, but the word 'meaning' is taken in its original non-textual and non-linguistic interpretation: [i.e.,] how one privileged trajectory is built, out of an indefinite number of possibilities; in that sense, semiotics is the study of order building" (Akrich and Latour 1992).

Semiotic Constraints on the Evolutionary Level

Similar, though nonidentical, dynamic systems approaches to the role of semiotic constraints in the evolution and functioning of biological organization have been taken by biochemist and complexity theorist Stuart Kauffman and colleagues, who write that:

The typical requirement for work itself is to construct those very constraints on the release of energy that then constitute further work. Information creation, we argue, arises in two ways: first information as natural selection assembling the very constraints on the release of energy that then constitutes work and the propagation of organization. Second, information in a more extended sense is "semiotic," that is, about the world (or internal state of the organism) and that requires an appropriate response. (2008)

and by the neuroscientist and biological anthropologist Terrence Deacon (2011), who

argues that biological "information" is a relational property that emerges from the interplay of three nested and recursive sets of constraints: (1) the set of purely physical constraints on signal dynamics, (2) the set of mathematical likelihood constraints on signal probability, and (3) the set of Darwinian fitness constraints required for the self-maintenance of the signal-using living system. By "generalizing the insight of Claude Shannon's equation of *information* with *entropy-reduction* and tracing its linkage [with] thermodynamic and evolutionary domains," Deacon hopes to show how physical constraints become informational (or semiotic) constraints by virtue of how they delimit certain systemic possibilities in the ways that an organism senses and responds to inputs from the environment.

Semiotic Constraints on the Human Sociological Level

The term "semiotic constraints" was first used in the humanities by the linguist and semiotician Algirdas Julien Greimas (1917–1962) to denote how the use of any given sign is always embedded in a larger system of signs, wherein the meaning possibilities that any given sign-user can assign to it are productively (and also prohibitively) constrained. These constraints intersect to form a "semiotic square" (or closed "phase space") of permitted meaning combinations.

Robotacist and Artificial Intelligence researcher Luc Steels and his colleagues have employed modified versions of Greimas' semiotic square as part of their experimental design for modeling the evolution of language using artificial agents (2004), while linguist and psychologist Joanna Rączaszek-Leonardi (2012) employs Howard Pattee's notion of semiotic constraints as material structures evolved for the use of controlling dynamics in her own rethinking of what it is that constitutes human language use.

"It is useless to search for meaning in symbols without complementary knowledge of the dynamics being constrained by the symbols" wrote Pattee in regards to the informational controls

that have evolved in biological systems (Pattee 1997). Likewise, argues Rączaszek-Leonardi, we should stop thinking of language as a set of formal, immaterial, rules and signs that speakers manipulate in the privacy of their minds, and start seeing it instead as a way that human beings deploy “soundwaves with a history” in order to constrain the dynamics of human interaction in particular goal-oriented directions.

“In order for those soundwaves to have acquired functionality, i.e., to have a meaningful history” so as to act reliably as effective semiotic constraints, writes Rączaszek-Leonardi:

they have to be stable and reliable under the laws of physics and principles of perception, and they have to have the power to evoke the desired effect. . . . Thus, what makes a natural language symbol a message, i.e., what makes it different from any other soundwave produced by a human, is that it has been selected and stabilized in the process of cultural evolution; these are, to paraphrase Pattee (1972) the ‘integrated constraints that endow what otherwise would indeed be ordinary [sounds] with their symbolic properties.’ (Rączaszek-Leonardi 2012)

Finally, in line with both his earlier work on brain/language coevolution (Deacon 1997) and his work on the nested nature of informational entropy-reduction processes discussed above, Terrence Deacon posits that the systemic requirements inherent to the avoidance of equivocation “about who did what to whom, when, with what [and] in which way” in any given system of symbolic communication constrains the variety of forms that informational entropy reduction systems such as languages can take. “Such semiotic constraints can be conceived as selection pressures,” argues Deacon, “and language origins and evolution in the larger sense must also have proceeded within these constraints at every stage” (2003).

Conclusion

The move towards investigating the informational and sign-processing (semiotic) dynamics produced by, and relevant to future, evolution has been growing steadily in the last two decades,

informed by ideas that were only partially sketched out by previous thinkers. Common to almost all of these approaches is the move away from a reified, mentalistic, and anthropocentric understanding of “signs and symbols” as creations of human language in the first instance, and towards a more naturalized understanding of the role that semiotic controls and processes play in the fundamental organization and evolution of living systems.

Semiotic Square

Donald Favareau
National University of Singapore,
Singapore, Singapore

Definition

The semiotic square is a conceptual tool that was first developed within the field of semiotics to depict the logical relations of opposition and implication inherent in any given sign or sign system. It has more recently been refashioned for use in the study of the evolution of language.

Introduction

The Semiotic Square is an analytic tool developed by linguist and semiotician Algirdas Julien Greimas (1917–1962) to depict how complex, nuanced, and even contradictory meanings can emerge from more primitive sets of oppositions (e.g., prescribed/forbidden) and their logical negations (e.g., not prescribed/not forbidden) in any given sign or sign system.

A graphic representation of the “possibility space of meaning” bounded by the four corners of opposition and implication as depicted below, the semiotic square is intended by Greimas to reveal “the elementary structure” of signification whereby terms and values are defined at least in part with respect to what they are not (Greimas [1966] 1983). For Greimas, this system of logical oppositions and their implications constitutes the “deep structure” of any coherent system of meaning, from the rules of a society to the narrative logic of a literary text. Accordingly, cultural

Semiotic Square, Fig. 1 A simplified version of Greimas' semiotic square, wherein any given “meaning” that can be assigned to a sign can be plotted along the coordinates of these axes (adapted from Greimas and Rastier 1968). In this framework, S_1 and S_2 represent a pair of signs holding contrary meanings (such as male/female or happy/sad) that necessarily imply the existence of their logical negations, $-S_1$ and $-S_2$. The resulting square depicts the field of meanings which can then be derived from logical relations of contrariety (dashed arrows), contradiction (solid arrows), and implication (dotted arrows)

theorist Fredric Jameson describes Greimas' semiotic square as “a virtual map of conceptual closure, or better still, of the closure of ideology itself” (Jameson 1976) (Fig. 1).

According to Greimas, individual actions, ideas, and identities arise from, and can only be meaningfully understood in relation to, the possibilities defined by the enclosing logical structure (Greimas and Rastier 1968) – and it is this insight that several researchers in the fields of Artificial Intelligence and Evolution of Language studies have been recently trying to operationalize.

The Relevance of the Semiotic Square in Language Evolution Studies

Roboticist Luc Steels and his collaborators have developed a modified version of Greimas's semiotic square in their experiments designed to have robotic agents create and “evolve” a shared language based on their interactions with the environment, which are then further codified by their interactions with one another (Gantelluci and Steels 2008; Steels 2011, 2015). In Steels' conceptualization, the four corners of the square

Semiotic Square, Fig. 2 Luc Steels and colleagues' version of semiotic square (adapted from Steels 2015), depicting the process by which any given sign derives its meaning, as explained in the text below

represent what he claims are the four mutually “scaffolded” linguistic entities through which shared meaning emerges and is sustained in a community of symbol users. These conceptual entities he calls the REFERENT, the IMAGE SEGMENT, the MEANING, and the UTTERANCE, all of which mutually influence each other in an ever on-going dynamic of perception, conceptualization, verbalization, and interpretation, as illustrated below.

Steels' version of the semiotic square differs in several important aspects from Greimas'. For whereas Greimas's square is a structuralist and formalist attempt at diagramming the topography of logical relations inherent in a given sign or sign system, Steels' square is an attempt to diagram the *evolutionary process* by which a sign's “meaning” is first bestowed and then recursively fine-tuned and employed within a group of interacting agents (Fig. 2).

As part of the “4E” (embodied, embedded, extended, and enactive) turn in cognitive science, Steels' model finds agents' initial perceptions of the world “grounded” in their embodied, sensorimotor interactions within the world. No objects in the external world are pregiven REFERENCES per se in Steels' semiotic processing framework. Rather, the plenum of available sensory input enabled by the agent's biology (or machinery, in the case of artificial agents) must be selectively organized by the agent (or by the agent's evolutionary history) so as to result in reliably successful interaction in an as-yet unlabeled world. The resulting *perceptual* IMAGE SEGMENT is so named to acknowledge that cognition deals with

only relevant and actively selected *aspects* of external objects, as those aspects are implicated in action sequences relevant to the agent, and not to a pictorial “representation” of the fullness of the external world per se (Steels 2006, 2011, 2015).

These perceptual IMAGE SEGMENTS then become *conceptualized* and given meaning within contexts of interaction via a *selectionist* dynamic. Categorical groupings and the acquisition of task-appropriate distinctions to be preserved for use in future similar interactions are the result of exuberant possibility-testing in the assignment of image segments to action repertoires, followed by the Darwinian pruning and “entrenchment of particular solutions by positive [and negative] feedback loops” not only over evolutionary time, but ontogenetically, as well (Steels 2015).

Both the *verbalization* and the *interpretation* of linguistic signals, likewise, are fine-tuned by the feedback based on the successful and unsuccessful interactions with other agents in using those symbols – and as these feedback cycles are ever-ongoing, generative, and recursive “semiotic networks” grow in the space defined by the interaction of these four mutually scaffolded processes of meaning (Steels 2004, 2006, 2011).

Conclusion

The disciplines of semiotics and of evolutionary psychology use term “semiotic square” somewhat differently. In semiotics, the square is used as an analytical tool to depict “the elementary structure of signification, marking off the oppositional logic that is at the heart of both narrative progression and semantic, thematic, or symbolic content” (Felluga 2015). In evolutionary psychology, the semiotic square is used to examine the real-world conditions under which sign-based meanings are created and evolve among a community of agents.

Senescence

Douglas E. Crews

Anthropology and Public Health, Department of Anthropology, Ohio State University, Columbus, OH, USA

Synonyms

Advanced age; Aging; Old age

Definition

Senescence is a multifactorial, deleterious, progressive, and cumulative alteration of cells and somatic structures that occurs in an age-related, but not age-determined, fashion, thereby decreasing individual probabilities of survival and reproduction with increasing age.

Senescence is a soma-wide process of functional losses secondary to decreased replicative capacity in dividing cells and accumulated exposures to stressors and related damage in both

dividing and nondividing cells as their time of survival increases. Senescent biology progresses as age-related declines in cellular, tissue, and organ fidelity and function lead to decreased reproductive potential, physiological and psychological dysregulation, and increased probability of death.

Introduction

Currently, across multiple populations, average life spans exceed 80 years (e.g., Italy, Japan, Sweden, women in the USA), and the verified maximum human life span has exceeded 121 years (France). Many factors have contributed to achieving these demographic landmarks. Primary among these have been social and political changes leading to improved public health, hygiene, and population nutrition. These, along with advancements in biotechnology, improved the understanding of the biological and social basis of disease, and applications of evidence-based medicine have contributed to large portions of many populations surviving past their 65th year. In Europe, improvements in average life span began during the nineteenth century as their current economies and social systems emerged and developed. Over the twentieth century, similar demographic trends have affected most of the world's populations (The World Bank 2013). In 1930, the average age at death was 60 years (men 58, women 61 years) in the USA, and only 50% of men and 57% of women survived to age 65 (Bell and Miller 2002). Across nations worldwide, age 65 years is a common criterion for retirement and social security programs, which provides a standard age for internal and cross-national comparisons and health evaluations. Eighty years later, life expectancy was 75 years among men and 80 years among women, with 80% and 88%, respectively, surviving to their 65th year (Bell and Miller 2002). Elsewhere average life spans are lower. In Kuwait life span averages 70 years and in Madagascar 64 years, with only 3% and 2%, respectively, surviving to age 65 years. Average life spans exceeding 70 years with maxima of 13 decades are a new

frontier for humankind. Just 40 kya (kiloyears ago), few individuals appeared to have survived past their 40th year (see Caspari and Lee 2004).

Today, those aged 65+ years are an increasing proportion of most national populations. During the 1920s, less than 5% of the US population was aged 65+ years; in 1950–1960, they exceeded 8% of the total; today they make up 14% (see Bell and Miller 2002; The World Bank 2013). Exceeding the USA, Japan's population includes 24% who are over 65 years and Sweden 21%, while Poland ties the USA at about 14%. Over the nineteenth and twentieth centuries, continued development of built environments, new agriculture methods, advances in medical treatment, and improved diets have reduced multiple stressors that limited human growth, development, and life span in previous environmental settings. These changes allowed today's elders (persons aged 65+ years) to escape many external hazards while receiving better nutritional and energetic intakes and medical care during their growth, development, and reproductive adulthood than did their ancestors.

Today, in high-income industrialized settings, over 80% of people survive to age 65, and 1 of every 4 persons who do so may expect to survive into their 90th year. Such long lives do not characterize our closest primate relatives, gorillas and chimpanzees. Even when housed in well-maintained zoological settings with healthcare, immunizations, balanced nutrition, and free from predation and most parasites, the oldest documented age for a gorilla is 60 years (Colo was born December 1956 at the Columbus Zoo and Aquarium and died there in 2017). Among humans, average life spans of women commonly exceed their reproductive spans by decades. Broad differences in the timing and pattern of life history events between humans and other large-bodied apes throughout life, particularly during the latter decades of life, did not arise solely due to long-term sociocultural developments. More likely, new patterns of sexuality, gestation, somatic growth and development, neurological and physiological systems, psychological structures, and sociality arose as humans and their immediate ancestors (hominins) exploited and adapted to prevailing conditions of

the late Pliocene, through the Pleistocene and Holocene. Humankind's ancestors exploited and adapted to niches significantly different from those exploited by competing hominins and other species. Among these divergent adaptations were upper limbs freed from weight-bearing and bipedalism. These were followed, several million years later, by a long-term trend toward brain expansion, suggesting not only increasing dependence on cognition and evolution of integrated physiological and psychological systems but also evolution of the theory of mind and intentionality (see Dunbar 1998). This evolutionary trend toward dependence on cognition required evolving hominins to allocate additional time and energy to neocortical tissues during their growth and development. This shift in resource allocation also initiated a trend toward secondarily altricial offspring, i.e., neurologically and physically immature at birth compared to other large-bodied apes. Eventually, evolutionary trends in hominin growth and development would require over a decade and a half of relatively high and constant parental investment before they were reproductively mature and socially capable of birthing or siring their own offspring (see Crews 2003; Crews and Bogin 2010).

By decreasing the rate of development and maturation from conception to reproductive adulthood, slow-maturing secondarily altricial offspring reshaped the hominin and human life history pattern compared to other large-bodied apes (see Crews 2003; Crews and Bogin 2010). As this life history pattern evolved over the last 2-plus million years, hominins showed an increasing life span potential (illustrated in Carey and Judge 2000, Fig. 8, p. B207). This long-term evolutionary trend, in conjunction with the development of language, sociocultural systems, built environments, and agriculture, produced the 80+ year average and 120+ year maximum life spans observed today. This contribution explores the evolutionary bases for extended human life spans and their concomitants, senescence and aging. The first focus is on the evolutionary basis of senescent biology being an indirect consequence of surviving and reproducing in a stressful world since the beginning of life. At its most

basic, senescence reflects a compromise between countervailing evolutionary pressures to survive and maintain the soma while also being reproductively successful. The model followed here is that stressor-related damage to cells, tissues, organs, and somatic systems along with their internal fragility produces the senescent phenotype (see also Kim and Jazwinski 2015). This is not a review of the biology of senescence, which would fill an encyclopedia of its own. Rather, it is an evolutionary perspective on how humans came to survive a century and more.

Evolution and Stressors

To survive and reproduce, early life (likely RNA-based replicators) responded to Earth's challenges by evolving multiple stressor-limiting adaptations (e.g., DNA, membranes, cells, multicellularity, mobility). To maintain fidelity and reproduction of its hereditary material, life evolved many forms, none of which escapes environmental and internal stressors. All life-forms evolved their current phenotypes and life history patterns, periods of growth, development, somatic maintenance, and reproductive effort as adaptations to stressors their ancestors experienced. As adaptive responses accumulated, new phenotypes emerged, including offspring who required extended time to grow, develop, and mature. As these increasingly complex phenotypes evolved, early phases of human life history were altered. Among these were, "secondarily altricial offspring" birthed at an earlier stage of development than other apes, extended periods of growth and development including addition of childhood and adolescence phases, and parental provisioning over 1.5-plus decades. To accommodate these evolutionary adaptations, later life history phases necessarily were delayed, and achievable life spans extended (see Carey and Judge 2000; Crews 2003; Crews and Bogin 2010). Across species, longevity (length of life) increased as successive generations evolved increasingly efficient adaptive responses to life's stressors. As more complex stress-limiting adaptations evolved (e.g., digestive and nervous systems, neurological

integration, skeletons, cognitive processing), they required longer periods of growth and development to fully mature. Among humans, these processes extended the premature stage of life leading to our current altricial offspring and delaying commencement of reproductive effort. Evolution of altricial offspring extended the time needed for parental investment and, apparently, also slowed the pace of human cellular senescence. By extending growth and development and delaying the onset of reproductive effort, this suite of adaptations altered human life history, slowed phenotypic aging, and extended human survival.

Although all organisms show deleterious cellular and somatic alterations with increasing survival, senescence is not viewed as an outcome of positive natural selection for cellular dysfunction, organismal frailty, decrepitude, or death in most organisms (see Williams 1957; Kirkwood and Austad 2000; Crews 2003; Arking 2006; Crews and Bogin 2010; Crews and Ice 2012). Rather, biological dysfunction likely developed as a by-product of natural selection for improved defenses against stressors limiting survival and reproductive success (see Williams 1957; Kirkwood and Austad 2000; Arking 2006). Senescence is an inherent by-product of life's fragility. As structural, somatic, physiological, psychological, and behavioral responses to senescent-promoting stressors improved, species' life span potential increased apace. These evolved responses to ancient and more recent stressors continue to mold human phenotypes, senescent biology, and life history. Senescence results from progressive, deleterious, cumulative, and age-related, but not age-determined, alterations associated with decreasing probabilities of reproduction and survival (Arking 2006; Crews and Ice 2012). Biological senescence is an ancient and universal cellular process associated with the loss of cellular integrity that proceeds at a biological, not a chronological, pace (Arking 2006). In dividing cells, senescence is paced by cycles of DNA replication and mitosis. Aging, or organismal senescence, is paced by losses of terminally differentiated (nondividing) cells, physiological function, strength, agility, and endurance and

increased somatic, physiological, and psychological dysregulation, frailty, morbidity, and mortality.

An introduction to life's evolution is necessary to review the evolutionary basis of senescence. Among life's earliest ancestors, individual existence likely was short and replication rapid. Eventually, these short-lived ancestors of life evolved adaptive responses to environmental stressors they encountered (see Hoeppner et al. 2012). One major adaptation was DNA to replace error-prone RNA as a hereditary molecule. More stable than RNA, DNA was a major evolutionary leap. As early replicators evolved internal processes and structures to protect themselves and their hereditary molecules (e.g., membranes, organelles, multicellularity), they increased their survival time (longevity). Eventually, these accumulated adaptive responses led to integrated vascular and neurophysiological systems, skin and skeletons, brains, and complex minds. The latter eventually provided humankind the ability to conceptualize and engage in intentional niche construction and build environments in which to better survive and reproduce. All extinct and existing species evolved as their progenitors responded adaptively to experienced environmental stressors. As biotic evolution continued, organisms capable of slowing their own demise lived sufficiently long to experience senescent biology as a by-product of their evolutionary success. Eventually an array of life-forms evolved, some that today survive only hours before reproducing and perishing, others that live a few days, and still others showing 100+ year life spans. Such differences in longevity and senescence are evolved products of life's continuing struggle to halt damage from stressors while surviving and reproducing in stressful environments.

Stressors and Senescent Biology

Although specifics differ, damage to life from environmental challenges continues today. For many ancient stressors (e.g., UV radiation, nonenzymatic glycation, reactive oxygen species, mutagens), life continues to evolve protective

responses. Still, damage to nuclear DNA (nDNA) and mitochondrial DNA (mtDNA), long-lived proteins and cells, and housekeeping systems increases with age. Many environmental stressors challenging human survival have declined or been altered in modern settings, for example, mega predators (e.g., leopards, tigers, bears) and infectious and parasitic organisms (e.g., bacteria, viruses, worms). At the same time, new stressors have emerged, exposures to pollution, human and animal wastes, built environments, artificial lighting, noise, and sociocultural stressors related to living in groups with high population density. Although all life-forms evolved because of their ancestors' adaptive responses, they still are not able to halt all related damage and losses. As a result, senescent processes are common to all biotic life, and different phenotypes and divergent LH patterns have evolved as populations and species followed their unique adaptive paths to survive and reproduce.

Multiple life history commonalities exist across species, including, for instance, a period of growth and development that culminates in a mature reproductive adult, who eventually succumbs to life's stressors. Commonly, this adult stage coincides with a period of maximum reproductive potential and effort when somatic and physiological function, psychological balance, and somatic resilience are at their maxima. Whether species' survival potential is days or decades, during immature life all organisms must possess sufficient resources, response systems, and/or social support to delay current stressors sufficiently long to mature and engage in reproductive effort. As survival time increases, progressive and cumulative damage to cells and tissues disrupts organismal function producing deleterious changes throughout the system; concurrently, organ and somatic damage secondary to external and internal stressors accumulate. Among multicellular life-forms, some long-lived (nondividing) cells senesce and lose their integrity, while others die as damage to their DNA, proteins, organelles, and membranes accumulates, leading to systemic physiological and psychological dysregulation. Similarly, as dividing cells

sustain damage over time, their replication time increases, and, eventually, they cease proliferating.

Stress-Limiting Systems

The multiple stress responses cells eventually evolved (e.g., multicellularity, organs and organ systems, defensive and repair systems, and psychological structures) constitute sets of overlapping survival and senescence-delaying mechanisms. Many previously evolved defensive adaptations likely have been lost as species went extinct. Other successful adaptations have been conserved and remain observable today as anti-stressor/anti-senescence responses, mechanisms, structures, and modules across species. Such features include the skin, fur, shells, tree bark, slime, vision, neurological structures, theory of mind, introspection, behavioral flexibility, verbal communication, and social systems. These anti-stressor adaptations continue to aid species survival and reproduction. Our cells, organs, and internal structures, whether skeletal, muscular, cardiovascular, neural, or psychological, evolved as adaptations to preserve life and reproduce in ecological settings where resources were scarce, stressors were immediate, life was short, built environments were nonexistent, and hominins were not a dominant species. In today's physically secure and nutritionally adequate settings, humans grow and develop sufficient organ and somatic capacity to exceed that necessary to survive and reproduce (see Crews 2003; Crews and Bogin 2010). Some organs (e.g., kidneys, liver, heart, bone) significantly exceed their minimal capacity to sustain life through the period of reproductive effort, including fledging of offspring. Among these, humans have an innate ability to use available energy in excess of what is needed for growth, development, and reproductive effort to build cellular, organ, somatic, and structural reserve capacity. In many of today's environmental settings, humans are able to accumulate energetic, somatic, physiological, and psychological capacities exceeding what they need to survive and reproduce. This accumulated

reserve capacity helps support somatic function during later decades of human post-reproductive life (see Crews 2003; Crews and Bogin 2010).

Human Evolution and Variation

Aspects of modern biology and senescence separating humans from other modern apes are based upon adaptive responses and peculiarities hominins evolved as their phylogenetic branch led to modern humans through the Pleistocene (approximately the past 2.6 million years, ending with commencement of the Holocene about 12,000 years ago). Humankind's current somatic, physiological, and psychological capacities coevolved as hominins responded to environments that stretched their adaptive limits, somatic reserves, and mental capacities to survive and reproduce in stressful environments (see Dunbar 1998; Crews 2003; Crews and Bogin 2010). Settings wherein, the hominin adaptive repertoire likely provided sufficient capacity for growth, development, survival, and reproductive effort, but little for late-life survival. In built environments of the twenty-first century, phenotypes based on this adaptive repertoire are able to exceed somatic and energetic capacities required to complete their growth, development, reproduction, and fledge offspring. In high-income settings today, this trend toward building reserve capacity continues into reproductive adulthood, providing a physiological reserve to support average life spans far exceeding those of our hominin ancestors. Today, a similar trend is observed among cats and dogs humans have domesticated as pets within built environments.

As living systems evolved, they faced not only old and new external challenges but also internal stressors generated by the processes evolved to defend themselves against external stressors. While responding to life's stressors over their 160 million years of existence, mammals evolved finely tuned and highly interactive neuroendocrine, immune, physiological, and psychological networks to modulate their internal milieu, behaviors, and external environment. Still, over their life spans, terminally differentiated and dividing

cells; the tissues, organs, and physiological and psychological systems they form; and somas they comprise lose their functional capabilities as maintenance, defense, and structural systems fail. Because the genomes of well-adapted organisms change slowly, some somatic structures, physiological and psychological capacities that evolved during earlier phases of hominin evolution, to then stressful environments, may not be ideal adaptations in current environmental and sociocultural settings. The Pleistocene is conceived by some as humankind's environment of evolutionary adaptedness, a time when our current biology and physiological and psychological systems evolved (see Foley 1995). Rapid improvements in life spans across not only high-income, industrialized, and wealthy nations but most populations have occurred in recent centuries, *prima facie* evidence that environmental and social stressors during earlier phases of evolution significantly constrained human somatic maintenance and life span. A doubling of life expectancy in the USA from the eighteenth to twentieth centuries, along with a current life expectancy 30% higher than in 1900, additionally attests to the severity of environmental and sociocultural influences affecting human survival as recently as a century ago.

Assessing Senescence

Gerontologists and geriatricians have proposed a variety of overlapping definitions for senescence and aging (reviewed in Crews 2003; Crews and Ice 2012). However, they have not agreed upon any specific quantitative measure for assessing the senescent phenotype that predicts mortality more accurately than age alone. Because senescence is a multifactorial outcome of innumerable interacting traits, no simple scale for assessing an individual's senescent phenotype is available. Rather, combinations of multiple physiological and somatic biomarkers currently are the best estimators of senescent dysregulation. Alterations in DNA expression patterns, mRNA and protein profiles, losses of mitochondria, and instability across the genome, including telomeres and

epigenetic markers, pace cellular senescence (see Arking 2006; López-Otín et al. 2013). At the organismal level, following growth and development, humans generally experience a period of health and somatic maintenance during their period of maximum reproductive effort. This commonly is followed by a period of somatic decline, physical and mental losses, and increasing frailty and chronic diseases, described as somatic aging.

Theoretically, aggregate biomarker indices integrate and reflect aspects of systems biology shared across all populations by tapping into individual variability secondary to genetic, familial, local, historical, cultural, and ecological backgrounds and current circumstances. These indices are proposed to assess clinical, and even subclinical, aspects of somatic, physiological, and psychological dysfunction. The main phenotypic assessments in current use to determine senescent losses are activities of daily living (ADLs; see Katz et al. 1963) and its secondary derivative, independent activities of daily living (IADLs). Others include biological age (see Levine and Crimmins 2014); metabolic syndrome (Camus 1966); the Framingham index (Wilson et al. 1998); allostatic load, a measure of physiological dysregulation (McEwen 2003); and frailty, a measure of somatic dysfunction (Walston 2005). Theoretically, when based on groupings of age-related biomarkers of functional and physical losses, stress response, and physiological dysregulation, these indices should assess current morbidity and predict future morbidity and mortality risks, cognitive and physical declines, and life span across populations. All are known to assess to at least some degree somatic and physiological losses over the life span. Two of the most recently proposed indices, allostatic load and frailty, are reviewed here.

Physiological Dysregulation and Senescence

Stressor exposures are a constant of life. Throughout growth and development and during adult life, exposures to persistent non-life-threatening stressors (e.g., hypoxia, cold, toxins) may improve somatic function and limit negative response in that specific setting, a process

of adaptability known as hormesis. Still, following a lifetime of stressors and stress responses (allostasis), our inability to halt all related damage leads to physiological dysregulation and increases risks for noncommunicable diseases and mortality (see Sterling and Eyer 1988; McEwen 1998, 2003; McEwen and Seeman 1999; Edes and Crews 2017). Jointly stressors and responses produce senescence (see Crews 2003; Kim and Jazwinski 2015), a multifactorial phenotype uniquely expressed by each individual.

By combining soma-wide sensory neurons, neurotransmitters, and hormones to modulate human physiology, the mammalian hypothalamic-pituitary-adrenal axis (HPA) regulates human allostasis (stress response) (see Sterling and Eyer 1988; McEwen 2003). Allostasis occurs in response to observable, quantifiable stressors (e.g., heat, hypoxia) and stressful situations (e.g., predator avoidance, antagonistic interactions, lack of food or water), along with individual mental states, including anticipated, perceived, and not quantifiable stressors, even when these do not occur. Allostasis alters hormonal and physiological set points (e.g., cortisol, epinephrine, blood pressure, glycemia, body temperature) in response to cognitive dissonance (Sterling and Eyer 1988; McEwen 1998, 2003) as external or internal stressors alter one's mindscape from moment to moment (discussed by Peters et al. 2017). Following allostasis, system components reset to their current optima. As a dynamic neurophysiological response to stressors, allostasis evolved to promote current survival by limiting systemic perturbations secondary to external and internal stressors (see Sterling and Eyer 1988; McEwen 1998; Peters et al. 2017). Over time, stressor exposures may overwhelm response systems, attenuating, over-activating, or halting allostasis, thereby promoting progressive physiological dysregulation, a hallmark of senescence (see Crews 2003; Austad 1997; Rose 1994; Arking 2010).

Allostatic load indices combine neuroendocrine and physiological biomarkers of stress response to assess cumulative somatic dysregulation theoretically attributed to stressors (see Sterling and Eyer 1988; McEwen 1998; Edes and Crews 2017). When stressful events occur,

they induce cognitive dissonance (Peters et al. 2017). When this signal reaches the hypothalamus, it promotes the release of corticotrophin-releasing hormone (CRH) to the anterior pituitary, stimulating the release of adrenocorticotrophic hormone (ACTH) to the circulation. ACTH activates the sympathetic-adrenal system to release cortisol, adrenaline, and noradrenaline, promoting behavioral and psychological (e.g., aggression, agitation, attentiveness, fear, fight-or-flight) and physiological responses (e.g., increased blood pressure and heart rate, reduced visceral blood flow) (see Sterling and Eyer 1988; McEwen 1998; Peters et al. 2017; Edes and Crews 2017). Excessive, constant, and lifelong allostatic responses tend to damage cells and organs, alter systemic regulation, and lead to progressive physiological dysregulation and increased allostatic load. This system can neither sustain its function indefinitely nor halt all stressor-related damage (Sterling and Eyer 1988).

Frailty, a Clinical Syndrome of Functional Losses

Since humans first recorded their ailments, they have remarked on losses of physiological function and physical abilities with increasing age (frailty). Frailty is a clinical phenotype of declining somatic function secondary to physical losses, including sarcopenia (loss or death of muscle cells) and osteoporosis (reduced bone matrix leading to fragility). Loss of function and the physical changes associated with frailty include unintended weight loss; declining strength, endurance, and walking speed; and reduced physical activity. Frailty indices are based upon tabulations of accumulated somatic deficits and losses that correlate significantly with age and tend to increase exponentially during the later years of human life (see Studenski et al. 2004; Walston 2005; Kim and Jazwinski 2015). Illustrating the likely genetic basis of frailty, offspring of short-lived parents show more rapid increases in frailty than do children of long-lived parents (Kim and Jazwinski 2015).

As a clinical phenotype, frailty increases with age and predicts future morbidity and mortality across samples (Walston 2005). Frailty

differs from allostatic load in that it measures current functional abilities, not physiology. Losses of functionality lead to reduced physical activity, less activity-related energy expenditure, poorer nutrition, weight loss, muscle weakness, and exhaustion. Various combinations of biomarkers, from as few as 5 to over 100, have been amalgamated into frailty indices (see Studenski et al. 2004; Walston 2005). Across multiple samples, frailty indices predict future losses of mobility, inability to complete ADLs/IADLs, more frequent falls and injuries, and higher morbidity and mortality, particularly among those aged over 65 years (Walston 2005, 2005; Studenski et al. 2004). Increased frailty and allostatic load over the life span are not solely a consequence of senescent biology; illness, trauma, accidents, social support, and psychological factors also contribute.

Senescence: An Evolutionary Trade-Off

Once growth and development are complete and reproductive effort commences, with increasing survival time, an evolutionary trade-off between somatic maintenance-survival and reproductive effort reduces investments in the former to support the latter. With increasing age post-maturity, cellular senescence and somatic wear and tear promote physiological dysregulation and reduce resilience leaving organisms more vulnerable to stressors. Given the variety of processes involved, human senescent phenotypes are as heterogeneous and similar as are fingerprints, facial features, and disease risks. Senescence is a change in systemic biology, not a process unique to a specific organ, physiological system, or psychological construct. Among most life-forms, alterations reflecting changes in systemic allocations of somatic resources from growth, development, and maintenance to investments in reproductive effort follow attainment of reproductive maturity. Switches in resource allocation usually are not as obvious among humans and nonhuman primates as they may be among other species. Still, age-related alterations in phenotypes and underlying genetic and molecular

regulators are fundamental to species life histories. An interesting example is a senescent-promoting genetic switch observed in nematodes, *C. elegans*. Following gamete production, germline stem cells produce a molecule halting production of heat-shock proteins, thereby limiting stress response and promoting somatic decline within 8 h of maturity (see Labbadia and Morimoto 2015). When this gene is blocked, heat-shock proteins remain active, stress resistance is maintained, and life is extended (Labbadia and Morimoto 2015). Likely, many early life-forms evolved gene-based single-locus switches and responses over their evolution. Some likely went extinct, while others likely have been passed on in evolutionarily modified forms.

Ancient adaptations, more recently evolved genetic propensities, and variable environmental settings continue to interact, modulating senescent biology across organisms. Among modern humans, growth, development, and reproductive and post-reproductive adulthood occur in environmental, ecological, and sociocultural settings differing significantly from conditions proposed for the “environment of evolutionary adaptedness.” In modern environments, humans experience variable stressor exposures and show broad variation in age-associated physical and psychological decrements and average life spans. Differences in familial disease risks and longevity attest to influences of shared genes and environments on life span. Across human samples, few specific SNPs, alleles, or haplotypes have shown consistent associations with life span, although distributions of multiple SNPs, candidate alleles, and haplotypes differ between younger and older cohorts within populations. Variants enriched among older cohorts in one population usually are not in others. Variability in genomic associations with longevity across populations suggests that strong gene-environment along with gene-environment-sociocultural interactions influence late-life survival. They also illustrate the need to apply evolutionary, systems biology, and social-ecological approaches and models to aid understanding of variability in human senescence and longevity.

As age increases, somatic and behavioral stress points that prime the soma for higher allostatic load, frailty, morbidity, and mortality reveal evolutionary compromises in basic physiological, immune, neural, and psychological functions. These stress points reflect evolutionary trade-offs related to competing needs for somatic growth, development, maintenance, defense, and reproductive effort (see Ellison 2014). Age-related processes of physiological dysregulation, fragility, and frailty simply reflect the inability of living systems to optimize their physiology, protect themselves from all internal and environmental insults, and show long-term reproductive success via evolutionary mechanisms. Given multiple trade-offs and evolutionary constraints (inertia) on the metabolism and structure of organisms, the individual cells of which they are composed likely are as optimized as possible for maintaining their function and reproducing their somas (see Vijg 2007). This applies equally to neurons and the cells composing our neurological structures, the brain, amygdala, hypothalamus, pituitary, and endocrine system. Similarly, continuing selective processes over hominid, hominin, and human evolution likely have optimized human neurological structures, along with their systemic connectivity, including the hypothalamus-pituitary-adrenal axis and the human mind. Theoretically, human neurological structures and the theory of mind they maintain also are adapted and optimized to receive and process selected sensory information, assess its survival and reproductive consequences, and produce as optimal a response as is currently possible.

Internal metabolism is another evolutionary stable trade-off, one between providing energy for cellular respiration and function while also generating reactive oxygen species (ROS) that damage DNA, membranes, and other cellular organelles, leading to cellular dysfunction, senescence, and death. Across the spectrum of life, organismal biology depends on evolutionary compromises (see Ellison 2014). At the DNA level, alleles conferring a net survival advantage during early life and reproductive ages, while also promoting detrimental phenotypes at later ages, are evolutionary advantaged because of their early

life effects (see Williams 1957). Due to early benefits, alleles showing such antagonistic pleiotropy increase in population gene pools despite their late-life ill effects. Williams (1957) articulated two associated hypotheses about evolution and senescence. First, later-life ill effects of alleles showing antagonistic pleiotropy will accumulate at ages just beyond those required to maintain their selective advantages. Second, as the late-acting detrimental effects of alleles exhibiting antagonistic pleiotropy reduce the relative reproductive success of their carriers, selection will push any associated ill effects to later ages. Observed in experimental settings with worms and fruit flies, antagonistic pleiotropy is a fitness trade-off that also affects humans. Proposed examples include testosterone levels in men, apolipoprotein variants across populations, reactive oxygen species (ROS) created during oxidative phosphorylation, and multiple late-life penetrant chronic and genetic conditions. Cellular senescence and somatic aging reflect multiple long-term evolutionary trade-offs across the spectrum of life. For most species, senescence follows periods of growth, development, and reproductive adulthood and effort associated with a relatively well-maintained soma. In humans, following about two decades of life to attain maximum somatic and reproductive function and 30+ additional years of reproductive effort, output, and parental investment, the soma shows a LH trade-off, increasing internal and external signs of dysfunction and physiological dysregulation.

Stressors and Life Span

In general, the evolved physiological and psychological propensities and systems of humans are the same across all people and populations. However, variable genes, along with their combinations, and developmental processes influence individual response, reactivity, resistance, and resilience to stressors. Stressor exposures of parents, grandparents, and more remote ancestors that marked their DNA or personalities (e.g., epigenetic markers, historical trauma) also may contribute to individual stressor responses. Variation

in life span also is affected by developmental processes and differential exposures to early life stressors and life events. As each individual lives postmaturity, their unique genetic endowment, developmental processes, stressor exposures, and related responses during life produce variability in their somatic function and dysregulation as their age increases.

Those experiencing greater adversity (e.g., undernutrition, malnutrition, infections, trauma, psychosocial, physical abuse) during early life, whether prenatal or postnatal, expend a larger proportion of their total lifetime energetic and physiological capacity resisting current stressors leaving little opportunity to accumulate reserve capacity (see Crews 2003; Crews and Bogin 2010). Conversely, those whose social and physical environments limit their exposures to early life stressors experience more opportunities to build reserve capacity, thereby promoting resilience and resistance to stressors and longer lives. Unfortunately, as age increases, defense and maintenance costs increase and reserve capacity declines as it is expended to meet current needs. Total daily energy expenditure (TDEE) is an ideal example of a physiological trade-off and decline with age. TDEE has three components, resting metabolic rate (RMR ~ 60–70%), activity energy expenditure (AEE ~ 20–30%), and diet-induced thermogenesis (DIT ~ 10%) (see Kim and Jazwinski 2015, Fig. 4). On average, all three components decrease with age among older adults. In the Louisiana Healthy Aging Study among participants aged 60+ years, RMR was higher at older ages but remained inversely associated with age (Kim and Jazwinski 2015). In one interpretation, as age increases and health declines, additional energy is required to maintain the soma, leaving less available for physical activity. Supporting this interpretation, in the Louisiana study, TDEE remained stable over the age span examined, suggesting physical activity decreased and additional energy for survival (RMR) was derived from AEE (Kim and Jazwinski 2015).

At all ages, but particularly among the aged, reduced physical activity sets the stage for sarcopenia and bone loss, components of

the frailty syndrome. Decreased physical activity begins a cycle of bone and muscle loss, reduced activity, and increasing frailty. Disrupted growth during early life is associated with poor somatic and neurological development, impaired physiological and psychological function, increased risk for chronic conditions, more rapid progress of allostatic load and frailty during adulthood, and early senescence (Crews 2003; Walston 2005; Crews and Ice 2012). Physiological and psychological processes by which early life insults, trauma, and mental abuse influence adult and late-life physical and mental morbidity and mortality are open questions. Long-term research across the biological and psychological sciences, including evolutionary psychology and biological anthropology, will be necessary to identify and untangle them.

Physiological Losses

After completion of reproduction, multiple age-correlated vulnerabilities appear in all life-forms. Over the human life span, physiological and psychological stress responses decline, and stress-related physiological dysregulation increases. Although all show age-related physiological losses, these vary between individuals and families and across local and regional settings. Within individuals, functional and physical losses do not pace chronological age; rather they occur at variable rates. Bone biology, biomechanical stability, and skeletal function provide a specific example. Many species evolved bony skeletons and structures for support and mobility, to encase their fragile organs, and to promote their long-term survival and reproductive success. Over its long evolutionary history, bone has been optimized to perform these functions. Among humans, bone and muscle loss, impaired mobility, and subsequent frailty are differentially distributed by age and sex and differ across samples of the same age and sex across settings and nationalities (Walston 2005; Kim and Jazwinski 2015). Variation occurs because genetic interactions and propensities, developmental insults/benefits, hormonal variability, lifestyles, environmental

stressor exposures, and individual patterns of genetic endowment and wear and tear influence muscle and bone biology and structure. The aging skeleton clearly illustrates cellular senescence and losses. Mobility is a major adaptation supporting organismal health and survival across species. Human mobility is dependent on more than a functioning skeleton to support the body with muscles and tendons to move it. Mobility also is dependent on physiological and psychological mechanisms that allow cognitive processing and produce the abilities to walk with a steady gait while moving with balance and agility. Impairment of these components increases with use, as do risks for accidents, injuries, and fractures. Concurrently, as age increases, injuries take longer to heal and may lead to additional gait and mobility problems, producing a cycle of functional losses and increased frailty. Sarcopenia, osteoporosis, and loss of strength with age correlate with psychosocial stress, allostatic load, frailty, and the onset and progression of noncommunicable diseases. As in past populations, wear and tear occurs on the joints of modern people, along with injury- and osteoporosis-related lesions and fractures, impairing mobility and leading to frailty. Even with available medical remedies and interventions, among Medicare-eligible beneficiaries ages 65+ years in the USA in 1999–2005, 25% had osteoporosis, while 42% of women and 10% of men who received benefits for 6–7 years had osteoporosis (Cheng et al. 2009).

Male-Female Mortality Differentials

Across all current sociocultural setting, women outlive men. However, over their longer life spans, women experience higher risks not only for osteoporosis but also other illnesses (e.g., urinary tract infections, depression, arthritis), morbidity (e.g., stroke, fatal heart attack), and disability than do same-aged men. Still, across all age groups, men die more frequently and earlier in life than do women. Longer life spans among women reflect evolved differences from men in their patterns of growth, development, reproductive effort, and reproductive output that

have differentially patterned their LH schedules and, thus, their senescent biology. Observed differences in disability, morbidity, and mortality, among men and women, represent a morbidity-mortality paradox. A tendency for females to outlive males is observed across diverse species from insects and birds to primates (see Oksuzyan et al. 2008). Data suggest that among humans, patterns of frailty and disability reflect physiological and psychological processes differing from those that increase risks for morbidity, disease, and death. This further suggests frailty may not directly predict mortality. Over their shorter lives, males generally show higher risks for congenital, chronic, and genetic conditions, more frequently engage in competition with conspecifics, engage in more risky behaviors, are more susceptible to environmental stressors, and expend greater proportions of their time and available energy on growth, development, and somatic maintenance and repair earlier in life than do women.

Conclusion

Multiple stressors challenge human somatic integrity over their finite life spans, underlying senescent biology and somatic aging. Our major response system to life's constant external and internal stressors is allostasis, a cognitively based, neurophysiological, and systemic response. Allostasis evolved to modulate, delay, and halt adverse physiological outcomes arising from stressor exposures. Human cells and the somas they build did not evolve to be immortal, nor did single-celled organisms. Immortal individual organisms are an evolutionary impossibility, but long life is not. As previously stated, biological life cannot optimize somatic growth, maintenance, reproduction, and reproductive effort via evolutionary processes. Eventually, all life succumbs to stressor exposures that promote cellular senescence and somatic aging. Across long-lived animal species, survival depends on genetic propensities that slow molecular damage and cellular losses while maintaining somatic integrity. Animals, not able to promote their own resilience and maintain their systemic biology

via genetic, physiological, psychological, and allostatic processes, show more rapid senescence; sarcopenia; bone loss; fraying of their tendons, ligaments, and supporting structures; cardiovascular and metabolic dysfunction; physiological dysregulation; allostatic load; frailty; and mortality.

During the late Pliocene, through the Pleistocene and Holocene, and into the Anthropocene, humans have experienced continually changing ecological settings and social/cultural systems. Adaptive responses to earlier unconstructed environments, from alleles to genotypes and epigenetic marks, may not be as “fit” (in the Darwinian sense) in current ecological and sociocultural settings including newly emerged and emerging stressors. Current human life history, including growth, development, adulthood, reproductive effort, and senescence, along with our stressor responses is based on 160MY of mammalian, 65+MY of primate, and 7+MY of evolution among bipedal hominins to modern humans. Multiple adaptations and physiological functions that enhanced survival and reproductive success of our ancestors during these earlier periods remain beneficial today. Other adaptations likely limit organismal survival and later-life reproductive effort. Given the premise that no organism is immortal, senescence and aging result from two major processes, exposures to environmental and internal stressors and the quality of their genome-based somatic resilience to stressors. Somatic structures, physiological allostasis, and psychological constructs evolved, and even sociocultural systems developed, in response to life’s pervasive stressors. Concurrently, systemic biological interactions across cells and tissues evolved to repair damage sustained from stressors, while psychological modules, constructs, and processes evolved to promote behaviors that enhance organismal resilience and slow, delay, or halt stressors.

Evolutionarily, a key component of success among humans has been their adaptive flexibility. Over hominin evolution, multiple genetically programed phenotypes and behaviors adaptive among our ancestral species likely became less able to track rapidly changing ecological

settings, particularly as the pace of sociocultural developments increased exponentially. Adaptive flexibility allowed humans to rapidly alter their behaviors as they experienced new challenges and environments. Most species show genetically programed responses to their common environmental stressors. Likely, humankind’s earlier ancestors did also. Today, some human behavioral responses likely are highly evolved gene-based propensities for responding to current informational inputs, acting like switches for turning on allostasis, e. g., jumping away from a snake, or detecting falsehoods. Among humans much of this genetic programming appears to have been overlain and to variable degrees replaced by flexible responses to environmental input at a variety of phenotypic levels. This flexibility includes fetal programming, developmentally variable responses to experienced environments, and individual and genomic epigenetic modulation of DNA expression. Physiological systems and psychological mechanisms attuned to environmental inputs during growth and development provide greater opportunity for phenotypic flexibility and rapid responses to changing environments than does the slower process of genetic change, perhaps even at so fine a level as generation-to-generation. Changing selective pressures over hominin evolution produced a trend toward secondarily altricial offspring with slower cellular senescence and promoted humankind to evolve a slower LH pattern than other apes. One based on a growth strategy of developmental responses to experienced environments over an extended period of maturation, rather than specific genetic adaptations to relatively constant environmental pressures. Today, genetic structures underlying human physiological and psychological responses to stressors continue to evolve, and life span continues to increase across human populations as developmental processes during growth occur in ever more secure constructed environments. At the same time, elders now survive sufficiently long to invest not only in their offspring but also their grand-offspring and kindred’s survival and reproduction, thereby enhancing selective pressures to extend human life.

Definition

The increase in responsiveness due to a strong, usually painful stimulus.

Introduction

Sensitization is a non-associative learning process that leads to increased responsiveness to a stimulus and is considered complementary to habituation. The increase in responsiveness or behavior is due to the exposure of a strong, most commonly noxious, stimulus that is causing pain. It is therefore logical to infer that sensitization's adaptive value is high, as it protects an organism from predators and other potential dangers Eisenstein, Eisenstein, Smith (2001).

Theoretical Background

The most prominent non-associative learning theory was composed by Groves and Thompson

(1970). Neurophysiological concepts were combined with concerns of human ethology and evolution to create the “dual process” theory. The dual process theory was the one which took into consideration both sensitization and habituation. This theory advocated that repeated stimulation would produce two independent processes that could both be active at the same time: decreased responsiveness (habituation) or increased responsiveness (sensitization). The authors believed that the two processes take place in different parts of the nervous system. Habituation is believed to take place in the so-called S-R system (reflex arc) that controls reflexes, whereas sensitization is believed to occur in the “state system” which is responsible for the level of readiness to respond. The state system requires arousal to become activated, while the S-R system is activated with the presentation of an eliciting stimulus. Further, habituation is thought to be stimulus-specific and involves learning, in contrast to sensitization which is not highly specific and does not require learning. However both are of relative permanence; they are expected to decay at the absence of stimulation. More characteristics of sensitization are presented below.

Characteristics of Sensitization

During sensitization an organism will only respond to high- or strong-intensity stimulus rather to low-intensity stimulus as it happens in the case of habituation. This constitutes a fundamental difference between the two processes, but it is not limited to that; sensitization can occur without necessarily having continual stimulation (a single, strong stimulus can sensitize the organism). Further, sensitization has a limited time course and relatively short-term effects; however that depends on the intensity of the stimulus Eisenstein, Eisenstein, Smith (2001). Petrinovich (1984), based on the “dual process” theory, outlines eight basic assumptions in relation to sensitization and are listed as follows:

1. Sensitization occurs in the “state” system and not in the “S-R” system.

2. During habituation training, sensitization appears initially but then deteriorates.
3. The amount and duration of sensitization are directly related to stimulus intensity. At high intensities, sensitization is directly related to stimulus intensity and frequency. However, at low intensities there may be little or no sensitization.
4. Sensitization decays spontaneously as soon as the sensitizing stimulus has stopped.
5. Repeated presentations of a sensitization stimulus result in gradual reduction of sensitization.
6. Response sensitization displays generalization.
7. Dishabituation is considered as an instance of sensitization.
8. Temporal conditioning of sensitization may occur.

Sensitization has not received as much attention as habituation did; however especially enlightening was the study of the neurophysiological basis of sensitization, in laboratory settings, with the mollusk *Aplysia* and the work of Kandel, as well as with the work of others scholars on *kindling* and *long-term potentiation*.

Long-Term Potentiation

Sensitization and long-term potentiation are similar processes but differ in their site of application. Sensitization occurs in specific pathways (state), while long-term potentiation occurs in synapses. However, the process of sensitization involves the mechanism of long-term potentiation.

Long-term potentiation of synaptic transmission is a major mechanism for investigating learning and memory in the synaptic level. Long-term potentiation is found in several regions of the brain, with the most prominent being the hippocampus thus its obvious involvement in the neural basis of some forms of memory Cooke & Bliss (2006). It is a form of synaptic plasticity and is defined as a persistent increase in synaptic strength following high-frequency stimulation of a chemical synapse.

High-frequency stimulation causes an increase in the efficiency of synaptic transmission, therefore enhancing the efficiency of the signal. For the induction of long-term potentiation, the activation of excitatory receptors is required Cooke & Bliss (2006). Bliss and Collingridge (1993) reported on the properties of long-term potentiation that differentiates it from other forms of synaptic plasticity: *input specificity* (it does not spread to other synapses), *associativity* (when a weak input of a single pathway is insufficient for the induction of long-term potentiation, simultaneous strong stimulation of another pathway can potentiate the weak stimulation), and *cooperativity* (apart from strong stimulation, long-term potentiation can be induced by the cooperation of many yet weaker stimulations). Since long-term potentiation occurs when a neuron shows an increased excitability over time due to a repeated behavior and the heightened synaptic transmission leads to the amplification of responses (i.e., pain), its involvement with the process of sensitization is high.

While the long-term potentiation of synapses in localized cell tissues seems to provide an elegant substrate for learning and memory, researchers turn their attention into experimentations with the whole living organism (in vivo experiments). Morris and colleagues (1986) provided for the first time some data from in vivo experiments in which it was indicated that long-term potentiation was essential for the construction of memories. Using rats, Morris and colleagues were able to examine their spatial memory by inserting an N-methyl-D-aspartate (NMDA) blocker drug in their hippocampus, a brain structure implicated in learning. NMDA is a glutamate receptor and an ion channel protein within nerve cells, and it is responsible for the control of synaptic plasticity and memory function. Initially rats were trained to swim in a water maze, in order to find the platform hidden beneath (in the center and the sides of the pool) and escape. As soon as the rats were able to locate the platform, they were separated in two groups. One group constituted the control group, while rats of the second group received the drug that blocks NMDA. Then both groups of rats were exposed to

the water maze spatial memory task with the rats of the control group being successful in locating the platform and escaping the pool. Contrary, the second group of rats exhibited impaired performance, as long-term potentiation could not be induced indicating thus damage in the hippocampus. This series of experiments indicated that long-term potentiation is implicated in learning and memory processes. Finally, dysfunctions in the process of long-term potentiation are thought to be implicated in mood disorders Post (2007) and neurodegenerative diseases as Parkinson's Cooke & Bliss (2006). Long-term potentiation is a fundamental process in a cellular level with implications in the process of learning.

Kindling

Both sensitization and kindling are forms of learning occurring in some parts of the nervous system, and the common characteristic they exhibit is the increase in responsiveness. Kindling can be thought of as a specific type of sensitization.

Kindling became known to the scientific world in the late 1960s through the published work of Goddard (1967) on the neurobiology of learning and later after the application of Goddard's model on the study of epilepsy. Goddard (1967) runs a series of experiments on rats where, in order to investigate their abilities to learn tasks, he administered electrical stimulations in various regions of their brains. With daily repetition of the electrical stimuli, the rats began seizing. That response, however, was astonishing, as the administered stimuli were too low to induce seizures. Even more surprising was the final observation of the rats having unprovoked seizures, that is, seizing without stimulation. In sensitization repetitive stimulation produces a full response. A full response can be elicited even with lower stimulus levels than the original stimulus. It appears that a decrease in the threshold of excitability develops leading to the automatic occurrence of the response, without external stimulation. Eventually, with further repetition, the response occurs spontaneously, in the absence of any stimulus demonstrating thus the phenomenon of kindling.

The changes caused by kindling seem to be long-term, but they are not permanent.

Kindling is universal across species (from frogs to humans) and throughout the brain, and it was the first neuroplasticity phenomenon suggested to give information on memory processes. At a first glance, it may seem awkward to imply that epileptic seizure activity could be interconnected learning; yet, it is plausible that the diverse mechanisms constituting kindling and learning interconnect and share several common mechanisms. In effect, under this conceptualization, both kindling and learning can potentially be considered as phenomena of neuroplasticity. However when kindling was compared to long-term potentiation as to which neuroplasticity phenomenon was more appropriate for modelling memory processes, long-term potentiation appeared to dominate, mostly because long-term potentiation was observed under normal neural activity contrary to kindling that was observed under seizures.

Further, kindling constitutes the model for the development or recurrence of medical (epilepsy) and psychiatric illnesses such as addictions and mood disorders, in which pathologies' recurrence is inherent Post (2007). Goddard's model has been referred to as the "kindling model for epileptogenesis" as it is the most frequently used model for temporal lobe epilepsy with complex partial seizures. It is used by scientists to study the effects of repeated seizures on the brain. What was demonstrated in the experiments with rats, the same applies for humans; a seizure may raise the possibility that more seizures will occur since repeated stimulation "lowers the threshold" and paves the way for seizures to reoccur (Dennison, Teskey, Cain, 1995, Racine, 1978). In an attempt to better understand the occurrence of epileptic seizures, many scientists including Racine (1978) have turned their attention to the underlying mechanisms of kindling, in neurotransmitter systems and intracellular mechanisms, as well as genes.

Goddard's experiments suggest that the processes underlying kindling and learning interconnect and possibly have similar underlying mechanisms. Kindling is of particular importance

in disorders where recurrence is involved, in addictions (relapse) and mood disorders (recurrent episodes), but its underlying mechanisms are yet to be refined by empirical investigations.

Drug Sensitization

Drug sensitization is a process frequently encountered in the literature of the field of addictions and pharmacology, and it is an essential process toward the understanding of drug action and use. Drug sensitization is a type of sensitization, and it refers to an increase in drug effect upon continual exposure to a drug in the organism, which was previously exposed to the drug. With repeated drug administration, gradual and incremental neuroadaptations are produced, which make animals hypersensitive to the specific drugs. Even though users or abusers will be keeping the same dosage levels, drug effects will be greater and greater; therefore they would become intoxicated even in small doses. Using repeatedly a drug but with some pauses in between causes greater sensitization compared to taking a single dosage or even taking repetitively the drug. Moreover, sensitization is promoted if periods of use are alternated with periods of abstinence. When a person who is sensitized let's say to cocaine and abstains from use for some time, he/she is at risk of fatal overdosing at reuse (Steketee & Kalivas, 2011, Robinson & Berridge, 2008). Known addictive substances, where sensitization has been observed in, are cocaine, amphetamines, morphine, nicotine, and even alcohol; importantly not all drugs are subject to sensitization, mostly stimulants. In addition, the selected route of drug administration as sensitization is influenced by the speed or the time it takes for a drug to reach the brain. Sensitization in the case of drugs is long lasting with its effects on behavior and cognition lasting for years even with abstinence; however factors such as the time lapse between dosages, the choice of drug, the age and sex of the user, and genetics influence the strength of sensitization. Due to these factors, vulnerability to sensitization differs between individuals Steketee & Kalivas (2011). That provides

an insight into the long-asked question of why some users become addicts while others do not get addicted. The sensitization of behavior and other psychological or psychomotor functions implies neural sensitization. Drugs seem to alter or reorganize neural systems and neurotransmitters, and even though causal relationships are yet to be established, neuroadaptations seem permanent. The permanency of changes in neurotransmitter circuits has crucial implications on the matter of cravings and relapse. Of special importance is the sensitization of the mesolimbic pathway of the mesotelencephalic dopamine system. Since dopamine is responsible for the motivation to go after pleasure and happiness and fulfill our “wants,” drugs come to jeopardize this process by making dopamine hyper-reactive, consequently increasing the prominence of drug cues, hence the intense cravings Robinson & Berridge (2008). In the matter of cravings and relapse, kindling is thought to be implicated. The aforementioned comprise the “incentive sensitization” theory of addiction developed by Berridge and Robinson (1998) and is noteworthy of further reading.

Drug sensitization is a complex process influencing drug users in a cellular level and in consequence in a behavioral level.

Conclusion

Sensitization is one of the simplest forms of non-associative learning, and it is of significant value as it has helped organisms to adapt in potentially dangerous situations and evolve. While sensitization's underlying mechanisms are still under investigation, research thus far has been able to provide data for the better understanding of learning phenomena and the appearance and treatment of pathologies.

Synonyms

Functional play; Practice play; Primary circular reactions; Sensorimotor stage

Definition

During the first year of life, much of children's playtime involves, mainly, the exploration of the world through the repetition of already assimilated sensory and motor activities, for the sheer pleasure of doing so.

Introduction

Child development is such a diverse and complex subject; no single theory sufficiently meets all of it. The most common theories focus primarily on cognitive development or on social development. Providing a good theoretical ground of development in either of these theoretical fields is an endless challenge, as each of them accounts for an enormous range of topics. Cognitive development entails the growth of various capabilities such as perception, language, attention, reasoning, conceptual understanding, problem-solving, and intelligence (Siegler et al. 2011). This chapter focuses on cognitive development and more specifically during the sensorimotor period, where according to the Piagetian perspective, the young infant explores its roots of adult intelligence (Siegler et al. 2011). We consider each stage's

fundamental assumptions about how young infants develop conceptually through play behaviors during the sensorimotor period.

An Evolutionary Perspective

Applying evolutionary theories on human condition to gain a better understanding has a long history in psychology. According to Groos (1901), play during animals' periods of immaturity, such as the juvenile period, was "critical" in shaping later development. This view was later incorporated into Piaget's (1962) theory of play in human development. Play is considered to be a central component for the immature child; in fact, an extended period of immaturity is common when play occurs in most species (Pellegrini et al. 2007).

According to the evolutionary biology perspective, there is a desire to play in specific ways and at specific points in life, common to a variety of mammals (LaFreniere 2011). Evolutionary biologists have long been intrigued to the origins and functions of play. In the evolutionary biology dictionary, the term "functions" with regard to play refers to when a behavior has typically added to the survival or reproductive success of an individual (genes) over many succeeding generations (Pellegrini and Smith 1998). Functions can also be defined in the context of beneficial outcomes during the life cycle of the individual player (Pellegrini and Smith 1998). As mentioned earlier, evolutionary biologists interested in the study of animal behavior (hereafter, ethologists) have suggested that play has been acquired by our species through the process of natural selection, in order to provide deferred benefits to the individual (LaFreniere 2011). In other words, through play a child develops and practices skills crucial to survival and reproduction in adulthood (Smith 2009).

Life history theory is a worldwide accepted analytical framework, used mainly in biology and evolutionary psychology since the 1970s (LaFreniere 2011). It considers an organism as an ever-changing life cycle – not as a static adult – suggesting that certain species-typical

characteristics evolve to favor somatic and reproductive efforts throughout life-span (LaFreniere 2011). Accordingly, Bogin (1999) postulated that because of a finite amount of time, energy, and resources available, individuals must make choices regarding their behavioral priorities and allocation of resources with respect to developmental periods and life goals suitable to those periods. For example, despite its clear costs, during the early-juvenile period, play is prioritized in all social primates, while social play takes up most of the time not spent eating and sleeping (LaFreniere 2011). This fact is considered to be crucial as the main basis for concluding an adaptive function of play, because natural selection favors only behaviors whose benefits clearly outweigh the associated costs (LaFreniere 2011). Play can be costly in terms of time and energy devoted to it as it diminishes the time, effort, and energy spent on other activities.

Despite such costs, there is a natural tendency of young mammals to engage in play as long as and as often as ecological constraints and opportunities afford (LaFreniere 2011); it is, in fact, indispensable to the development and good functioning of a healthy adult.

Jean Piaget's Theory

It wasn't until Jean Piaget's work appeared in the 1920s for the world to have a recognizable field of cognitive development. Jean Piaget (1896–1980) began his journey from an early age. It was his keen interest in observing animals in their natural environment and his enthusiasm in philosophy that led him into his studies of clinical psychology. While in Paris, he became more interested in the mistakes children make in response to intelligence tests and came to suggest that exploring children's errors could offer an insight into their cognitive processes. By integrating the disciplines of psychology, biology, and epistemology – a branch of philosophy concerned with knowledge – Piaget aimed to establish a scientific approach into understanding how humans acquire and understand knowledge. Almost a century later, Piaget's theory remains one of the most influential and

best-known cognitive developmental theories in the field. Yet, it is notable that current reinterpretations of Piaget's theory came to suggest that children might have more capabilities at a younger age than Piaget thought (Smith et al. 2015).

According to the cognitive theorist, children are active mentally from birth onward as they are physically and that their experiences and activities indeed contribute to their own development. His proposition has been labeled as *constructivist*, as it represents children as constructing knowledge for themselves through their own experiences (Siegler et al. 2011). Piaget further explains that children use – mainly – three constructive processes including generating hypotheses, performing experiments, and drawing conclusions from observations (Siegler et al. 2011). This description depicts the process of scientific problem-solving and this in fact, the dominant metaphor in Piaget's theory: the “child as scientist” (Siegler et al. 2011) where children do not depend on instructions from adults or others, but they rather learn on their own.

Central Developmental Ideas

In addition to the above, Piaget suggested significant insights into the roles of nature and nurture and of continuities and discontinuities in development (Siegler et al. 2011). For instance, he believed that nature and nurture interact to favor human cognitive development. Nurture includes every experience the child encounters in the environment (Siegler et al. 2011). Nature includes the child's maturing brain and body and the ability to perceive, act, and, learn from their activities as well as meeting the two basic functions that are essential components of cognitive growth: *adaptation* and *organization* (Siegler et al. 2011). Adaptation is when children are able to respond to environmental demands in ways that meet their own goals, while organization is when they are able to accommodate specific observations into coherent knowledge (Siegler et al. 2011). It has been suggested that because both of these functions involve children's reaction to experience or otherwise nurture, it can be further said that part of

children's nature is to respond to their nurture (Siegler et al. 2011).

As mentioned previously, Piaget also offered important insights into the roles of continuity and discontinuity in development. Three processes form the main sources of continuity – *assimilation*, *accommodation*, and *equilibrium* – and work together to favor development (Siegler et al. 2011). Assimilation refers to the process by which people integrate new incoming information into conceptual ideas they already understand, while accommodation refers to the process by which they apply their current knowledge in response to new experiences (Siegler et al. 2011). Equilibrium is the process by which people balance assimilation and accommodation to create stable understanding (Siegler et al. 2011). In fact, this process happens in three phases. First, young children feel contended with their current knowledge about a phenomenon; Piaget named this a state of equilibrium, as children do not face any gaps between what they see and their understanding (Siegler et al. 2011). Once new information is encountered, children face a stage of disequilibrium as their understanding about a phenomenon is not sufficient, and thus they fail to generate a superior alternative (Siegler et al. 2011). Finally, children develop a more mature, inclusive understanding, which provides a more stable equilibrium, in terms of being able to understand a broader range of observations in the surrounding environment.

Although Piaget emphasized elements of continuity in cognitive development, the most well-known part of his work concerns discontinuous aspects, which he presented as distinct *stages* of cognitive development. Each stage represents a meaningful way of getting an insight into one's experiences, and each transition between stages represents a discontinuous thoughtful leap from one meaningful way of understanding to the next, higher one (Siegler et al. 2011).

Piaget suggested a number of central properties, which define as well as underlie the four cognitive developmental stages. He believed that children at different ages think qualitatively different, and he named this property *qualitative change*. For instance, he explains that children in

early stages of their cognitive development perceive the concept of morality in terms of the consequences of a person's behavior, whereas older children perceive it in terms of the person's intent (Siegler et al. 2011). A 5-year old would believe that someone who, by accident, broke a jar of cookies is naughtier than somebody who deliberately stole a single cookie; an 8-year old would have the opposite judgment. This difference suggests a qualitative change as the two children are basing their moral assessments on different criteria (Siegler et al. 2011). Then, Piaget suggested that the type of thinking characteristic children acquire from each stage influences their thinking across varied topics and contexts; Piaget named this property *broad applicability* (Siegler et al. 2011). Additionally, before entering a new stage, children engage into a brief transitional period (Siegler et al. 2011). During this period children fluctuate between the type of thinking characteristic of the new, more advanced stage and the type of thinking characteristic of the old, less advanced one (Siegler et al. 2011). This property has been labeled as *brief transitions*. Lastly, Piaget suggested that everyone progresses through the four stages with the same order and cannot skip a stage, what we call *invariant sequence* (Siegler et al. 2011).

Stages of Cognitive Development

As Piaget suggested people progress through four cognitive developmental stages: the *sensorimotor* stage, the *preoperational* stage, the *concrete operational* stage, and the *formal operational* stage. In each stage, children demonstrate new abilities, which allow them to experience and understand the world in qualitatively different ways than they had before (Siegler et al. 2011).

1. In the sensorimotor stage – from birth to 2 years of age – infants experience basic sensory and motor abilities through which adult intelligence develops. Through these abilities young children explore the world and gain information about the objects and people in it (Siegler et al. 2011). In this stage, young

- children live mainly in the here and now, while their intelligence levels are based on their immediate actions and perceptions (Siegler et al. 2011).
2. In the preoperational stage – from 2 to 7 years of age – preschoolers can remember their experiences for longer periods of time and develop more sophisticated ideas as they can now represent their experiences in language and mental imagery (Siegler et al. 2011). Yet, according to Piaget, they still lack the ability to form *mental operations*, that is, forms of reasoning as part of an organized system of mental activities. For example, during the preoperational stage, a young child would be unable to form the idea that pouring a liquid from one glass into a different-shaped glass does not change the amount of liquid (Siegler et al. 2011).
 3. In the concrete operational stage – from 7 to 12 years of age – children can reason logically about concrete objects and events (Siegler et al. 2011). For example, they can now understand that the amount of liquid is unchanged when it is poured from one glass to a differently shaped one. Yet, they still cannot think in abstract terms, neither to test out their beliefs through scientific experiments.
 4. In the last stage of cognitive development, known as the formal operational stage – age 12 and beyond – children can think sophisticatedly about abstract ideas as well as hypothetical scenarios (Siegler et al. 2011). They can also test out their beliefs and gain appropriate conclusions by forming scientific experiments.

With this overview of Piaget's cognitive development theory, we can examine in greater extent the changes that occur during the sensorimotor period. Specifically, we consider how newborn children behave during this stage in terms of sensorimotor play and exploration.

Sensorimotor Play

During their first year of life, children engage mainly, in what Piaget called sensorimotor play

or practice play (Piaget 1962). This consists mainly of already experienced, sensory and motor activities, which are repeated for the absolute pleasure of doing so (Hughes 2010). Piaget (1962) suggested that this form of play is integral for the child's intellectual development and that the young child moves through a number of different substages of sensorimotor progression. Sensorimotor play is acquired gradually during the first 18 months of life before the newborn child moves to symbolic or make-believe play (Hughes 2010). In fact, Piaget gave a detailed description of the process by which children develop their own capacity for thinking by carefully observing how his own children were behaving (Smith et al. 2015). Based on these observations, he divided the sensorimotor play period into three behaviors, which he called circular reactions (Hughes 2010).

Primary Circular Reactions

This is the earliest form of sensorimotor play – the *primary circular reaction*. During this period, which begins from birth and usually lasts up to 4 months of age, an infant accidentally discovers a pleasing sensory or motor reflex activity that is related to its own body (Hughes 2010). The infant experiences enjoyment and, thus, repeats the activity (Hughes 2010). Piaget used the term “circular” to emphasize the way that children repeat newly reflex experiences, notably the ones that are pleasing such as scratching or grasping (Smith et al. 2015). The term “primary” relates to basic behaviors that the child learns to exhibit, from the reflexes of the initial period (Smith et al. 2015). Based on his own 8-week-old son's behavior, Piaget illustrated the concept of primary circular reaction by explaining: “Laurent ‘scratches and tries to grasp, let's go, scratches and grasps again, etc. . . . At first, this can only be observed during feeding. Laurent gently scratches his mother bare shoulder. [The next day] . . . Laurent scratches the sheet which is folded over the blankets, then grasps and hold it for a moment, then lets it go, scratches it again, and recommences without interruption” (Piaget 1963, p. 191).

In behaving as he did, Laurent's actions could be perceived, as play with objects rather than play

centered on his own body (Hughes 2010). Yet, according to Piaget this is not the case as he explains that the play is the physical action such as the grasping or scratching (Hughes 2010). According to this idea, an infant is interested in the action itself, rather than being interested in the object they are performing the action on (Hughes 2010). For example, the same action is performed on any object that happens to be around the infant. In this matter, we can appreciate that children, even early on in their life, can manipulate objects once they are given to them. Indeed, such reflex behaviors are purposeless and lack intellectual awareness – two essential elements that characterize object play (Hughes 2010).

Secondary Circular Reactions

From the age of 4 until the age of 10 months, children move to the next stage of circular reactions that is distinctly different (Piaget 1962). They are now interested on objects and the consequences of their actions, instead of being focused on their own body and repeating actions based on early reflexes (Smith et al. 2015). They engage in what Piaget called *secondary circular reactions*, the intentional alteration in their surroundings by making interesting things happen such as moving a hanging object by hitting it (Smith et al. 2015). Particularly, secondary circular reactions refer to the young infant's enthusiasm to repeat newly initiated actions, aiming to influence their surrounding environment.

To illustrate the difference between primary and secondary circular reactions, Piaget described the behavior of his daughter, Jacqueline, at 5 months of age. He describes: "Jacqueline looks at a doll attached to a string, which is stretched from the hood to the handle of the cradle. The doll is at approximately the same level as the child's feet. Jacqueline moves her feet and finally strikes the doll, whose movement she immediately notices. . . The activity of the feet grows increasingly regular whereas Jacqueline's eyes are fixed on the doll. Moreover, when I remove the doll Jacqueline occupies herself quite differently; when I replace it, after a moment, she immediately starts to move her leg again" (Piaget 1936/1952, p. 182). Thus, we can see that Jacqueline's interest

has moved from her own body toward her surrounding environment and the consequences of her actions. In behaving as she did, the young girl seemed to have detected a relation between her movement and the doll's and was involved in secondary circular reaction.

During secondary circular reaction substage, as children continue to grow, they also start to combine different behavioral schemas, what Piaget called *coordination of secondary circular reactions* (Smith et al. 2015). In the following example, we can see how Jacqueline combined different schemas such as "sucking" or "grasping" an object in a series of coordinated actions when a new toy is introduced to her at 8 months of age: "Jacqueline grasps an unfamiliar cigarette case which I present to her. At first, she examines it very attentively, turns it over, then holds it in both hands while making the sound 'apff' (a kind of hiss which she usually makes in the presence of people). After that she rubs it against the wicker of her cradle then draws herself up while looking at it, then swings it above her and finally puts into her mouth" (Piaget 1936/1952, p. 284). Jacqueline's behavior illustrates how children begin to combine several schemas to achieve goals or get through new situations.

Tertiary Circular Reactions

While the newborn child between 8 and 12 months of age would engage in a repetition of their actions in order to enjoy an interesting outcome, the young 1-year old progresses to the next level. Although children would still repeat the previous stage, they are not repeating it precisely, but instead, they try to vary the activity, a new behavior known as a *tertiary circular reaction* (Hughes 2010). Children's behaviors are now more flexible, and this could lead to new results (Smith et al. 2015). By repeating actions in alternative ways young children are, essentially, applying already-established schema to new situations and needs (Smith et al. 2015).

Consider the example of Piaget's daughter Jacqueline – now 13 months old – in her bath: "Jacqueline engages in many experiments with celluloid toys floating on the water. . . Not only does she drop her toys from a height to see the water splash or displace them with her hand in order to

make them swim, but, she pushes them halfway down in order to see them rise to the surface. Between the ages of a year and a year and a half, she amuses herself by filling her sponge with water and pressing it against her chest, by running water from the faucet. . . along her arm, etc.” (Piaget 1936, p. 273). The playful element in this form of circular reaction is evident, as the child seems to enjoy their time with novel objects as well as actively trying to create new interesting experiences.

As the young child progresses through the previous stages of sensorimotor play, they learn to act directly on their surrounding environment via their sensory and motor schemas. According to Piaget, the sensorimotor play period ends when children finally achieve what we call *internal representation* (Smith et al. 2015). Internal representation refers to the child’s ability to act indirectly on the world because they have now a mental representation of the world, and this ability is not acquired until the newborn child reaches the age of 18–24 months (Smith et al. 2015). This means that children are able to manipulate their mental representation of the world such as being able to think and plan.

Object Permanence

Piaget (1954) made an interesting, yet controversial, claim suggesting that children through the age of 8 months experience a deficiency in their thinking or, in other words, lacking *object permanence*. Object permanence refers to the knowledge that objects continue to exist even when we cannot see them (Siegler et al. 2011), and according to the cognitive theorist, very young infants ignore any object that was out of sight. For instance, if an infant was reaching for a doll but then the doll was covered with a cloth, the infant would immediately lose interest in it and look away. This claim was based on Piaget’s observations of his own son Laurent, and he explains the young child’s behavior in the following account: “At age 7 months, 28 days, I offer him a little bell behind a cushion. So long as he sees the little bell, however small it may be, he tries to grasp it. But if the little bell disappears

completely he stops all searching. I then resume the experiment using my hand as a screen. Laurent’s arm is outstretched and about to grasp the little bell at the moment I make it disappear behind my hand that is open and at a distance about 15 cm. from him. He immediately withdraws his arm, as though the little bell no longer existed” (Piaget 1954, p. 39). Therefore, it has been suggested that infants younger than 8 months can only represent objects they can perceive at the moment (Siegler et al. 2011). The adage “out of sight, out of mind” is literally true.

According to Piaget (1954), it was only through the last substages of the sensorimotor play period that children demonstrated an awareness that the object continued to exist even when it was out of sight (Smith et al. 2015). Looking for an object that cannot be seen directly suggests that the child has a mental representation of the object. In fact, the idea of object permanence supports Piaget’s claim that by 18–24 months of age, young children are able to manipulate their mental representation of the world, known as internal representation.

By the end of their first year of life, infants explore for hidden objects rather than behave as if they had disappeared, indicating that they can mentally represent the object’s enduring existence even when they are out of sight. These first object representations are sensitive, however, as reflected by the *A – not – B error* (Siegler et al. 2011). In this error, once the young child reaches the age of 8–12 months and learn to reach for and find a hidden object several times in one place (location A), when they see the object hidden at a different place (location B) and they are restricted from immediately searching for it, they usually reach where the object was originally found (location A) (Siegler et al. 2011). Not until around the first year of life do young children initially explore at the object’s current location.

At around 1 year of age, infants begin to actively explore their surrounding environment including the potential ways in which objects can be used (Siegler et al. 2011). Piaget described young children as “scientists” and suggested that their own activity greatly contributes to their development (Siegler et al. 2011). To illustrate this emerging competency, Piaget described how

his son Laurent would vary the positions from which he dropped different objects to observe what would happen. Consider this description: “Laurent is lying on his back... He grasps in succession a celluloid swan, a box, etc..., stretches out his arm and lets them fall. He distinctly varies the position of the fall. When the object falls in a new position (for example, on this pillow), he lets it fall two or three more times on the same place, as though to study the spatial relation” (Piaget 1963, pp. 268–269). Piaget viewed such actions as the beginnings of scientific experimentation rather than as bad behavior.

By the end of the sensorimotor stage (18–24 months of age) as the young child develops, according to Piaget, they are now able to form enduring mental representations (Siegler et al. 2011). The evidence for this new mental capability is what Piaget called *deferred imitation*. This is when young children carry out a behavior they observed other people doing, minutes, hours, or even days after it occurred (Siegler et al. 2011). Piaget provides a good example of this by illustrating an observation of 1-year-old Jacqueline: “Jacqueline had a visit from a little boy... who, in the course of the afternoon, got into a terrible temper. He screamed as he tried to get out of a playpen and pushed it backward, stamping his feet... The next day, she herself screamed in her playpen and tried to move it, stamping her foot lightly several times in succession” (Piaget 1951, p. 63). According to Piaget, Jacqueline had never before shown such a temper. The reason for doing so, probably, is because she had watched and remembered the boy’s behavior, retained a representation of it overnight, and imitated it the next day; in other words, she had a mental representation of what she had observed the previous day (Smith et al. 2015).

Conclusion

When we consider Piaget’s account of cognitive development during the sensorimotor period or otherwise infancy, the infant progresses from very simple and basic reflex actions at birth, to more complex behaviors at the end of the stage. At

first, infants’ motor or sensory activities are related to their own bodies with concrete goals being the ultimate outcome, such as shaking a rattle and listening to the sound it makes. Later, infants’ activities are mainly focused on the surrounding world with more abstract goals such as differing the heights from which objects are dropped and watching what happens as well as how the different effects vary. Young children also acquire the ability to form mental representations, progressing from “out of sight, out of mind” to remembering another person’s behavior and imitating it the day after it occurred. It is only toward the end of the period that children develop this ability to mentally represent the world as well as to manipulate their thoughts and construct their own knowledge in response to their experiences.

Definition

Mating preference for a courtship signal trait evolves as a preexisting sensory bias from a non-mating context and is then exploited by the opposite sex, increasing mating opportunities.

Introduction

An important evolutionary driver of animal signal diversity is female mate choice. Throughout the animal kingdom, mating success between the sexes is asymmetric; most females in a population procure mates while some males mate multiply and many males fail to mate at all. This asymmetry results in differential selection on male traits and influences the evolution of male courtship signals (Andersson 1994). Virtually all mating systems include some component of communication whereby receivers must be able to detect and discriminate the sender's courtship signal. This communication is critical for female mate choice, and in particular, females must be able to recognize members of their own species. Failure to perform this recognition often imposes severe fitness costs on the female, as a hybrid mating typically yields offspring with reduced vigor. Species recognition occurs through the assessment of specific characteristics of courtship signals. These signals can take on a myriad of different forms and may be communicated through virtually any sensory system (Ryan 1985; Basolo 1990; Partan and Marler 1999; ter Hofstede et al. 2015).

A large body of research has examined how the tuning of animal sensory systems generates signal recognition and influence mate choice (Capranica and Moffat 1983; Ryan 1990; Guilford and Dawkins 1991; Shaw 1995; Endler and Basolo 1998; Ryan and Cummings 2013). This work has connected signal evolution to receiver bias or more broadly, receiver psychology. Classically, sensory bias has been considered in three non-mutually exclusive contexts: sensory trap, sensory drive, and sensory exploitation (Endler and Basolo 1998). A sensory trap occurs when males produce a signal that elicits a positive mating response from a female because the signal mimics

a stimulus from another context (Christy 1995). For example, in fiddler crabs (*Uca* spp.), females preferentially choose males that build pillars since the pillars mimic natural structures that allow females to escape predation. Sensory drive integrates evolutionary processes, environmental factors, and sensory systems that can lead to changes in signals and then behavior. For example, in two species of African cichlid, *Pundamilia* spp., female preference for red and blue nuptial coloring coincide with the spectral depth gradient in the natural habitat of the fish (Seehausen et al. 2008). This in turn may result in sexual selection on male coloration through female mate choice via sensory drive. Finally, Ryan (1990) proposed sensory exploitation to explain how male courtship signals evolve to exploit preexisting biases of the female's sensory system. Mate choice via sensory exploitation predicts that male signals should evolve to increase stimulation of the female's sensory systems and specifically should evolve to align with female sensory systems in regions that are most sensitive. Thus, females should be predisposed to prefer a particular courtship trait or character if it better stimulates her nervous system. Additionally, this preexisting bias must be present before the signal arises, otherwise the trait will fail to spread in the population. This review of the sensory exploitation hypothesis will focus on the sensory physiology, organismal behavior, and perception in three animal groups that have been extensively studied.

Animal Mating Systems via Sensory Exploitation

Anuran amphibians: Frogs have proved to be an outstanding system to investigate the sensory basis of mate choice (Ryan 1985; Bee 2015). Many frogs breed in a lek system where multiple males congregate at a pond and produce courtship vocalizations. The conspicuous inflated vocal sac, characteristic of most calling frogs, is easily seen located between the frog's mouth and forelimbs (Fig. 1).

Often multiple species occupy a breeding pond, where males vigorously call and defend small territories against rival conspecifics. This vocal competition generates an acoustically complex environment. Females arrive at the pond and choose a mate by listening for males, distinguishing among different species, as well as individual calls of conspecific males.

Frogs possess two inner ear organs, the amphibian papilla (AP) and the basilar papilla (BP). These organs are tuned to relatively low sound frequencies (AP) or relatively higher frequencies (BP). Within a species, there is a strong correlation between the tuning of the inner ear organs and the frequency of the male courtship call; quite simply, if a male's call falls within the region of best sensitivity of the female ear, he is most likely to be detected and hence attract a mate. This correlation between signal properties and neural sensitivity has been described as matched filter detection (Capranica and Moffat 1983).

Sensory Exploitation Hypothesis, Fig. 1 A calling male túngara frog with waveform and spectrogram of call (*inset*)

As a system of study, the túngara frog, *Physalemus pustulosus*, has played an important role in elucidating the sensory basis of mate choice (Ryan 1985). In this species, males produce a two-note courtship call (Fig. 2).

The first note is called a “whine,” and males always produce this while calling. The second note, the “chuck,” can be voluntarily appended to the whine. Males almost never make a chuck in isolation and females do not respond to a chuck produced artificially in the absence of a whine. The whine is both necessary and sufficient for mate attraction. When males append one or more chucks to a whine, however, this makes the call five times more attractive than the whine alone. The dominant frequency of the whine matches the best sensitivity of the túngara AP, and the dominant frequency of the chuck closely matches the greatest sensitivity of the BP (Fig 2). Interestingly, a related species, *Physalaemus coloradorem*, also makes a “whine-type” advertisement call, but males do not make chucks. If a chuck is artificially appended to the *P. coloradorem* call, females prefer it, even though they have never been exposed to a chuck under natural conditions. Further, the BP in *P. coloradorem* exhibits similar tuning frequencies to the túngara frog, indicating that the artificial chuck is stimulating this additional inner ear organ. This illustrates that for túngara frogs, the chuck spread in the population when a mutation generated an early chuck-type note in the call, matching the spectral sensitivity (e.g., preexisting bias) of the BP.

In addition to frequency cues, female frogs have also been shown to use temporal aspects of call pulses for species recognition. This has been especially well studied in gray treefrogs. These consist of two species, Cope’s gray treefrog *Hyla chrysoscelis* and the gray treefrog, *Hyla versicolor*. *H. versicolor* is a tetraploid of the diploid *H. chrysoscelis*. The species are morphologically identical but produce distinct pulsed courtship calls. Males of *H. chrysoscelis* produce a courtship call typically consisting of around 50 pulses/s. Males of *H. versicolor* typically produce calls of about 20 pulses/s, although this can vary with temperature in both species (Gerhardt

and Huber 2002). Both species use pulse rate as a mechanism for identifying conspecifics, with females showing strong mating preferences for conspecific pulse rates.

In more detailed neurobiology experiments, researchers have been able to examine the neural underpinnings of hearing perception in frogs (Wilczynski and Capranica 1984). For example, counting neurons have been identified in the auditory midbrain that responds to species-specific pulse rates in two species of frogs (Edwards et al. 2002). Recently, Schrodde et al. (2014) used the minimally invasive auditory brainstem response (ABR) to develop a frequency tuning curve for Cope’s gray treefrog. They found two peak sensitivities, corresponding to the expected tuning of the two inner ear organs and also closely matching the frequencies of male’s advertisement calls (Schrodde et al. 2014). In addition, this matched previously documented frequency preferences by females.

Orthopteran insects: Like frogs, Orthopteran insects (crickets and katydids) have provided a unique system to study behavior and signal evolution (Gerhardt and Huber 2002). In most species, males produce acoustic signals to attract mates by rubbing their fore wings together. The sound is produced by scraping one wing, which possess a series of teeth, against the anal margin of the other wing, which acts like a scraper. Generally, crickets communicate at frequencies around 5 kHz, and katydid calls are broadband signals with a frequency spectrum that may extend from the sonic to ultrasonic range (10–60 kHz). Both crickets and katydids possess tympanal ears for hearing on their legs. This sensory system, particularly in crickets, is tuned for the frequency of the male call. For example, in the cricket *Gryllus bimaculatus*, it has been shown that the tympanal sensitivity was best tuned to the carrier frequency of the male song, about 5.3 kHz, thus songs produced at higher or lower frequencies were not detected as easily. In addition to frequency, crickets and katydids produce chirps in specific temporal patterns, and detecting these species-specific pulse patterns is also an important part of recognition. In an elegant review, Hedwig

Sensory Exploitation Hypothesis, Fig. 2 Waveform (*upper*) and spectrogram (*lower*) of a male tungara frog call. In the spectrogram, the two boxes correspond to the peak hearing sensitivities of the tungara frog's two inner ear organs, *A* basilar papilla, *B* amphibian papilla. Although harmonic energy from the whine extends into the BP sensitivity range (*box A*), there is relatively little energy there to stimulate the BP. Instead, the majority of the call energy in the BP sensitivity range is contained within the chuck. Conversely, most of the energy from the whine falls within the range of the AP sensitivity (*box B*), thus the whine primarily stimulates the AP

(2016) showed that the species recognition system in crickets works as a set of serial filters, with each filter responding to specific features of the song such as frequency, chirp duration, and repetition rate.

Katydidids are categorized by a high diversity of acoustic communication signals. In a comparison between partially sympatric sibling species, *Neoconocephalus robustus* and *N. bivocatus*, Deily and Schul (2006) found that they exhibit different call recognition mechanisms. *N. robustus* males produce calls with a single pulse rate and females of the same species are attracted to calls without amplitude modulation. In *N. bivocatus* females require amplitude modulation for call recognition. More broadly, in a phylogenetic comparative analysis of katydid call diversity, three important call properties were identified: call structure, pulse pattern, and pulse rate (Frederick and Schul 2016). This analysis compared 17 katydid species in the genus *Neoconocephalus* and revealed convergent evolution in call traits. Call diversity and the ability of a species to recognize conspecifics appeared to limit species diversity in particular locations. Two species with the same call trait do not co-occur. This coupled with changes in call structure and pulse rate produce clear acoustical niches, generating distinct species recognition.

Thus far, sensory exploitation has been described via neural tuning and female mate choice, the context in which it is normally considered. In the Hawaiian cricket, *Teleogryllus oceanicus*, a preexisting bias in males, however, has rendered a mutation adaptive. Like most crickets, males of this species produce songs to attract a mate. This song also attracts parasitoid flies (Zuk et al. 1993). A wing mutation, rendering some males silent, occurred in the population. Normally this mutation would have been eliminated from the population as silent males would fail to procure mates and pass on the trait. A preexisting behavior, the propensity for males act as satellites, rendered this trait adaptive, however, and allowed it to spread rapidly in the population. With satellite behavior, males sometimes approach another calling male, remain silent, and intercept females attracted to the caller. By exploiting the calling behavior of other males,

the mutated silent males maintain their ability to procure a mate and also reduce their chance of attracting parasitoid flies (Tinghitella and Zuk 2009).

Another example of sensory exploitation in crickets is the conversion of a vibration startle response to a mate-pairing signal (ter Hofstede et al. 2015). Generally, female field crickets approach males with a low-frequency call and avoid high-frequency calls. In lebinthine crickets, the males produce an extremely high-frequency call and in response, the females produce a vibration instead of moving towards the male. The male then follows the vibrational signal to the female ter Hofstede et al. (2015) documented that field crickets closely related to the lebinthine crickets show an acoustic startle response to high-frequency sound and generate vibrations similar to those produced by female lebinthine crickets. The lebinthine vibrational signal thus likely arose from the preexisting startle response.

Fish: In contrast to crickets and frogs, courtship communication in fish primarily occurs via visual signals. Male Trinidadian guppies (*Poecilia reticulata*) display complex color patterns to females, and females prefer males with intense orange colors. Both male and female adult guppies are more responsive to orange-colored objects, even outside mating contexts (Rodd et al. 2002). The orange color is generated from carotenoid pigments in the diet and guppies are attracted to orange-colored food items. The cabrehash tree and several other trees produce bright orange fruit, but it is a rare, high quality food source for guppies. Thus, this preference for orange objects may have arisen in the context of food detection.

Another fish system, the genus *Xipophorus*, contains species where males bear a decorative extension of the caudal fin (swordtails) as well as unsworded species (platyfish). Female swordtails typically prefer to mate with males possessing longer swords. Interestingly, female platyfish, whose males lack swords, also prefer to mate with males who have had a sword artificially affixed to their tail. The sword is a derived character in this group, demonstrating that the female bias for the ornament predated the

evolution of the sword (Basolo 1990). Recent data also support the hypothesis of sensory exploitation for the sword ornament in a group distantly related to *Xipophorus*. Mollies are composed of two clades, the long-fin clade and the short-fin clade, which differ in the presence of the sword phenotype. The tamesi molly, *Poecilia latipunctata*, was historically classified as a short-fin molly based on morphology and ecology but is grouped with long-fin mollies based on molecular and behavioral data. Tamesi molly females prefer the sword ornament, even though the males of this species do not express the trait (Makowicz et al. 2015).

African rift lake cichlids have undergone rapid evolutionary radiation, evolving hundreds of species within a relatively short time frame. This group exhibits a wide array of ecological and morphological variation, as well as variation in sexually selected courtship signals. These courtship signals are especially prominent as variable color patterns and have evolved through mate choice. For example, Egger et al. (2011) tested female preference for “egg spots,” the prominent light-colored spots that males of many species exhibit on their anal fins. They presented female haplochromine cichlids, *Pseudocrenilabrus multicolor*, with images of males where egg spots were artificially added; males of this basal species lack egg spots. Even though males of their own species lack them, females expressed a pre-existing preference for these egg spots. The authors suggest that this preference may have arisen because the yellow-orange color of these spots was previously adaptive for locating carotenoid rich foods. Other work examining spectral tuning of retinal photoreceptors have provided clear evidence that different species have diverged in their sensitivities to particular wavelengths of light and these sensitivities have driven subsequent mate preference behaviors and color evolution (Seehausen et al. 2008).

Perception and Behavior

Information on sensory tuning, mate preference, and phylogenetic relationships have been

important in elucidating the process of mate choice via sensory exploitation (reviewed in Ryan and Cummings 2013). More recently, some of this work has incorporated techniques from the human psychophysics literature, providing glimpses into the role of sensory perception in mate choice and signal evolution. Historically, understanding sensations and perception were considered to be outside the realm of science because these phenomena are “private” to each individual. Researchers working in human psychophysics developed experimental techniques to test perception; specifically they measured stimuli and asked individuals if they could detect or discriminate, and hence perceive them (e.g., Fay 1988). The biology of some nonhuman organisms also lends itself well to these psychophysical methods and has allowed researchers to make important cross-taxonomic comparisons in auditory processing, perception, and mate choice. Here again, Orthopteran insects and Anuran amphibians have proved successful models (Wytenbach and Farris 2004; Bee 2015).

Phelps et al. (2006), for example, presented female túngara frogs with a series of digitally manipulated calls. This series consisted of calls that were digitally “morphed,” from a normal túngara frog call into the call of another species that the female túngara frogs do not recognize. By presenting female túngara frogs with this series of calls, they were able to test the limits of acoustic recognition and discrimination. This allowed the researchers to then build a cognitive framework defining the acoustic recognition space in this species.

In another series of studies with the túngara frog, Farris and colleagues demonstrated a surprising auditory grouping behavior (Farris et al. 2002; Farris and Ryan 2011). Many animals use spatial cues to group segments of sound together and generate a coherent “auditory object,” that is, assigning a particular complex sound to its source location (Bregman 1990). In a series of clever experiments, Farris et al. (2002) explored the basis of auditory grouping in the túngara frog. As discussed previously in the chapter, females respond to the male’s whine call, but

not an isolated chuck. In their experiments, Farris et al. (2002) presented females with a whine and chuck that were physically separated and females responded to the spatially separated chuck as if it were produced in the same location as the whine. Based on these data from a single whine and chuck, it appeared that female túngara frogs do not use spatial cues in auditory grouping. In a subsequent study, they presented females with a whine and two spatially separated chucks. In this case, females appeared to take advantage of relative comparisons, favoring chucks that were placed closer to whines in either space or time (Farris and Ryan 2011). This indicates that auditory grouping was not absent in túngara frogs. Instead, like humans communicating in noise, strategies for assigning sounds to their source by túngara frogs seem to be flexible.

In humans, a well-known phenomenon, the continuity illusion or auditory induction, occurs when brief silent gaps in sound are filled with white noise. The auditory system then fills in the masked gaps and generates the perception of an unfragmented “auditory object.” This process in humans likely improves speech comprehension in noisy environments where segments of speech become masked by noise (Bregman 1990). Baugh et al. (2016) tested auditory induction in the túngara frog and surprisingly found that they seem to lack this ability. Because túngara frogs communicate in noisy environments, analogous to noisy human speech conditions, it might be predicted that frogs would incorporate a similar mechanism for improving acoustic discrimination. Interestingly, Taylor and Ryan (2013) performed a similar type of test, but combined both acoustic and visual signals. In this study, they “sandwiched” a visual stimulus of a calling male frog between two temporally separate male call components, the whine and chuck. Normally, the temporally separated call components fail to elicit full recognition of the call. When the visual stimulus was placed in between the separated whine and chuck, however, this perceptually rescued the acoustic components and restored recognition, indicating the presence of a multisensory continuity illusion.

Conclusion

Since the early 1990s, tests of sensory exploitation as a mechanism for signal evolution via mate choice have required a multidisciplinary approach, employing methods from neurobiology, behavior, and phylogenetics (Ryan 1990; Shaw 1995). Further investigation of sensory exploitation still requires this integrative approach, since the evolution of the signal and receiver preference may not be closely coupled, the disconnect occurring as the preference predates the signal origin. Ryan and Cummings (2013) support a conceptual shift from the broad term sensory bias to perceptual bias to further expand our understanding of signal evolution via mate choice. The inclusion of theory from human psychophysics is an example of this shift, but there are also new approaches that will further the field. One is to gain fine-scale information about the focal communication system by utilizing genomic or transcriptomic tools. This is already being done by some behavioral researchers (Hofmann et al. 2014) and more are coming.

Another area under investigation is a focus on the female brain at the neuromolecular level, linking neural processes responsible for sensory processing to motor output leading to female mate preference behavior (Cummings 2015). Finally, an exciting area of research is beginning to focus on individual differences in sensory perception and mate choice. This area of research could focus on repeated measures of female preference, individual differences in central and peripheral signal processing, and/or individual genomic links to behavioral preference (Ronald et al. 2012; Patricelli et al. 2016). The previous several decades have provided profound insights into the role of sensory exploitation in mate choice and signal evolution. Current and developing technologies and concepts that allow researchers to link individual differences in genes, physiology, and behavior promise to offer an unprecedented understanding of this evolutionary process.

Sequential Tool Use

Gema Martin-Ordas
Centre for Behaviour and Evolution Newcastle
University, Newcastle upon Tyne, UK

Synonyms

[Associative tool behavior](#)

Definition

The use of two or more tools to obtain a goal.

Introduction

Tool use is a widespread behavior among many nonhuman animal species (e.g., Shumaker et al. 2011). However, nonhuman primates and corvids have produced the most extraordinary examples of tool-use behaviors. In the wild, for example, chimpanzees at Gombe (Tanzania) have been reported to plunge little sticks into termite mounds in order to access the termites. Similar behaviors have been described in New Caledonian crows – they use small twigs to extract insects from holes in logs. These two examples represent instances of using a single tool to obtain food (Shumaker et al. 2011).

Although more uncommon, instances in which the use of two or more tools is required to obtain a particular goal – so-called *associative tool behavior* (Shumaker et al. 2011) – have also been demonstrated in animals. Associative tool behaviors encompass cases in which animals use a tool to support another tool, so-called *metatool use*, to modify or manufacture another tool, *secondary tool use*, as well as instances in which two or more tools are used in sequence and each tool is used in a different mode, so-called *serial tool use* or *tool set*. An example that falls in the last category has been described in the chimpanzees of the Goulougo Triangle (Republic of Congo). When trying to access the termites from subterranean nests, the chimpanzees first use a puncturing stick on the ground and second a fishing probe that allows them to obtain the termites (Sanz et al. 2004).

Importantly, a tool can also be used to obtain a second out-of-reach tool, which subsequently will serve to obtain an out-of-reach goal – so-called *sequential tool use*. According to Shumaker et al. (2011), in the animal tool-use research, the categories *metatool use* and *sequential tool use* have been mistaken and considered to be equivalent categories. However, as pointed out by Shumaker et al. (2011), “a metatool is not used

to acquire another tool but rather to increase the efficiency or effectiveness of the second tool” (p. 20). Thus, an orangutan using a stick to push a paper towel into a puddle of edible liquid is not an example of sequential tool use but an example of metatool use (Shumaker et al. 2011). In addition, whereas sequential tool use has been reported in primates and corvids, metatool use has only been observed in primates.

Empirical Evidence

Sequential tool use has been commonly tested in lab settings by presenting subjects with an out-of-reach reward, an immediately available tool, and an out-of-reach second tool. The first tool is not useful to obtain the reward but useful to reach the second tool, which can then be used to obtain the reward. For example, Bird and Emery (2009) showed that rooks could spontaneously drop a large stone into a container to release a small stone, which was then used to acquire food. New Caledonian crows could use a directly available short stick to reach for an out-of-reach long stick, and then use the long tool to reach for a reward placed in a vertical tube (e.g., Taylor et al. 2007). Likewise, Bluff et al. (2007) showed that New Caledonian crows could first obtain a tool by pulling up a string; next, use the tool to extract a longer second tool from a toolbox; and finally, use the long tool to obtain food from a hole. Using a very different setup, Wimpenny et al. (2009) presented New Caledonian crows with the following situation: an out-of-reach reward, two tools that were available but too short to reach the food, and four out-of-reach tools differing in functionality. The distance of the food and/or which tools (and how many) were needed to obtain the food defined the sequence of actions required for successful performance. Wimpenny et al. (2009) found that crows could use up to three tools in sequence in order to obtain the reward.

As mentioned above, nonhuman primates have also been reported to use tools to access other tools. For example, Martin-Ordas et al. (2012) showed that apes could *spontaneously* use up to

five tools in sequence. Macaques (Hihara et al. 2003) and cotton-top tamarins (Santos et al. 2005) can also do so – although only after receiving some training.

Cognitive Mechanisms Involved in Sequential Tool Use

Wimpenny et al. 2009 (see also Shumaker et al. 2011) argued that the use of two or more tools is more cognitively demanding than the use of a single tool – the number of objects required to succeed will certainly increase the level of difficulty of the task (see also Fragaszy and Cummins-Sebree 2005). Taylor et al. (2007; see also Bird and Emery 2009) have also suggested that using tools in sequence is a demanding task because the individual has to (1) understand that the tool can be used to access food but also to access nonfood items, (2) inhibit the drive to use the tool to access the food, and (3) plan the sequence of actions, that is, anticipate the series of sub-actions needed to achieve a final goal. Importantly, Wimpenny et al. (2009) stressed that most of the research done on sequential tool use did not help to unravel the cognitive underpinnings of animal performance. In particular, they argued that learning history or trial error – as opposed to planning or causal understanding – could explain animals’ performance in those particular tasks. Wimpenny et al.’s (2009) task controlled for some of these issues (see also Martin-Ordas et al. 2012). Consequently, the authors concluded that, at least, the performance of one subject “in particular leaves open the possibility that crows may solve sequential tool problems by planning their actions, rather than having to build up associations by repeated experience.” (p. e6471).

Conclusions

Sequential tool use is defined as the ability to use a tool in order to obtain a second out-of-reach tool, which subsequently will serve to obtain an out-of-reach goal. Whether planning, reasoning, or associative learning are cognitive mechanisms

involved in sequential tool use is still an open question. As such, future research should develop experimental paradigms to further investigate the cognitive mechanisms underlying this particular tool-use behavior.

Synonyms

[Dominant](#); [Serotonergic system](#); [Serotonin transporter](#); [Social dominance structure](#); [Social hierarchy](#)

Definition

Dominance describes high status of an individual in social hierarchy that allows for priority access to limited resources such as food, mates, and space. Serotonin, a monoamine neurotransmitter, contributes to the formation of social hierarchy and positively affects dominance in humans and other primates.

Introduction

Social hierarchy is a key element in the organization of many human and nonhuman groups that undertake collective and cooperative activities. Dominant group members standing at the top of the hierarchy are privileged with various benefits including priority access to limited resources (food, mates, space) over the subordinate

members. In order to maintain their position, dominant individuals exercise behavioral tactics that rely on subtle interplay between cooperation, affiliation, and aggression directed toward subordinates. In contrast, submission, although limits the access to resources, allows weaker and less skillful individuals to minimize consequences of aggressive encounters with conspecifics.

Misinterpretation or ignorance of the social dominance structure has profound consequences for individual's life including aggression from conspecifics, exclusion from the social group, or death (Watanabe and Yamamoto 2015). Because of this, one can expect that during evolution, there had to be a selection pressure on efficient neurophysiological mechanisms for recognizing and interpreting cues for social status in conspecifics and expressing social status of oneself. Neuroscientific studies conducted during the last decade helped to elucidate these mechanism and pointed to the important role of serotonergic system in establishing of the social hierarchy both in primates and in humans (Kiser et al. 2012).

Serotonin and Social Hierarchy

Serotonin (5-HT) is a conservative monoamine neurotransmitter derived from the amino acid L-tryptophan, found in all bilateral animals. In the central nervous system (CNS), primary sources of 5-HT production are raphe nuclei located in the brainstem; however, 90 % of serotonin is synthesized outside CNS, in gastrointestinal tracts. The synthesis of serotonin in the brain is dependent on the availability of its precursor amino acid, tryptophan. Serotonin is reabsorbed from synapses through serotonin transporter located on the pre-synaptic neuron, and levels of synaptic serotonin might be regulated via selective serotonin reuptake inhibitors (SSRI). Degradation of 5-HT in the brain is mediated by monoamine oxidase A (MAOA), which results in producing 5-hydroxyindoleacetic acid (5-HIAA).

Serotonin was found to directly support dominance structure in primate groups. Studies conducted in vervet monkeys (*Cercopithecus aethiops*) demonstrated that alpha-male

individuals had higher levels of blood and brain serotonin that decreased when dominant position was lost (Raleigh 1984). Furthermore, experimentally induced rise in 5-HT level promoted dominance acquisition in these animals (Raleigh et al. 1991). Similar effects were observed in humans. Experimental treatments with tryptophan and selective serotonin reuptake inhibitor (both act to rise 5-HT level) were associated with increased self-assessed dominance (Moskowitz et al. 2003), increased dominance judgments by peers, and dominant pattern in a stranger-dyadic social interaction (Tse and Bond 2002) in healthy men and women.

Studies in several different areas such as serotonin involvement in processing of facial cues, voice cues and mechanisms of aggression and cooperation elucidates how serotonergic system affects recognition and the establishment of social dominance structure.

Serotonin Affects Facial Cues Recognition

Social status is most frequently signaled in close proximity. In such conditions, individual's face represents an ideal source of transmission of the dominance signals and facial expression constitutes one of the best recognizable cues to communicate social status. Numerous studies confirmed that people, similarly to primates, read and identify cues of dominance from various characteristics of the face such as shape, facial expression, or gestures (Keating 1985; Little et al. 2007; Re et al. 2013). It is hypothesized that these facial clues evolved from the preparatory or support responses associated with attack or defense. Facial characteristics such as chin prominence, heaviness of brow ridges, and facial muscularity were also found to be predictive on current and future social status and reproductive success of their holders (Mueller and Mazur 1997; Rule and Ambady 2010).

Facial expression perception depends on serotonergic system, and 5-HT level influences recognition of emotion from the face (Harmer 2008). Higher synaptic 5-HT level induced by repeated administration of selective serotonin reuptake inhibitors (SSRI) is associated with decreased accuracy of recognizing angry, fearful, and

disgusted faces (Harmer et al. 2003) and increased tendency to interpret ambiguous faces as happy (Harmer et al. 2004). In addition, the same experimental procedure is associated with reduced neurophysiological response to fearful faces from the amygdala, hippocampus, and medial prefrontal cortex observed in functional magnetic resonance imaging (fMRI) (Harmer et al. 2006). These observations suggest that dominant individuals characterized by higher 5-HT levels (Raleigh 1984) might be less responsive to angry and fearful faces and react with lower anxiety to threats from conspecifics. In contrast, submissive individuals with lower 5-HT levels might be more sensitive to angry expressions, which allow them to avoid aggressive attacks from dominants.

Serotonin Affects Voice Processing

Voice is another important cue to social status. Voice pitch in male primates, including humans, is associated with testosterone level (Dabbs and Mallinger 1999) and perceived attractiveness and dominance (Puts et al. 2006), thus might be indicative of reproductive success. Moreover, studies on CEO's of companies registered on the American Stock Exchange showed that voice may also predict professional status and income – CEO's with lower voices make more money and enjoy longer tenures at the companies (Mayew et al. 2013). Interestingly, polymorphism in serotonin transporter gene (5-HTTLPR), which regulates synaptic serotonin concentrations and possibly modulates dominance hierarchy (Miller-Butterworth et al. 2007), is also associated with voice perception and processing. In particular, study finds that carriers of the short allele of 5-HTTLPR, associated with increased synaptic serotonin level, showed a decreased differentiation in the event-related potential (ERP) responses elicited by happy and angry tone of voice. The number of short alleles was associated with linear decrease in the amplitude of the ERP in response to a happy voice. This suggests that the facilitatory effects of processing positive (happy) voices were reduced in individuals carrying the short allele. In contrast, facilitation through positive voices was strongest for individuals homozygous for the long allele (Grossmann et al. 2013).

Serotonin Affects Aggression, Cooperation, and Affiliation

To reach and maintain dominant rank in social hierarchy, individuals use specific tactics that include mixture of affiliative, cooperative, and aggressive behavior. The intensity of each of these behaviors depends on species, its social organization, and ecological niche. While general aggressiveness and physical strength defines position of the individual in the social hierarchy of simply organized groups, these characteristics are insufficient in communities where cooperative skills are required (Kiser et al. 2012).

Serotonergic system was demonstrated to support all of these behaviors, i.e., aggression, cooperation, and affiliation, however not in a simple manner. In vervet monkeys, subordinate group members treated with serotonin enhancers achieved dominance by first increasing affiliative behavior toward group members and creating support group. During this period, aggressive behavior significantly decreased, while affiliative behavior (approaching and grooming) was significantly increased. Only after coalitions with other individuals were established dominant individuals engaged in aggressive encounters with conspecifics (Raleigh et al. 1991). Similar effect was observed in humans – application of selective serotonin reuptake inhibitor to the subjects was associated with increase in peer-rated dominance and increased eye contact when subjects were speaking. At the same time, subjects were more prone to reduce their award in favor of their opponents and increase number of cooperative messages sent to opponents during the mixed-motive games (Tse and Bond 2002). These observations concur with general effects of serotonin on aggression and cooperation. Experimental studies conducted in humans and nonhuman primates confirm that serotonin depletion increases aggression (Siever 2008), learning of cooperation, and perception of trustworthiness (Wood et al. 2006).

Conclusion

Neurophysiological studies conducted in non-human primates and in humans suggest an

important role of serotonergic system in shaping dominance hierarchy. Results of these studies demonstrate serotonin involvement in mechanism of achieving and maintaining dominant rank in social hierarchy. They also highlight possible alterations in dominant and submissive processing of emotions from nonverbal characteristics, such as face expression and voice pitch that signal social status. These alterations might result from differences in serotonergic system activity between dominant and submissive individuals.

Service-for-Prestige Theory of Leader-Follower Relations

Michael E. Price
Centre for Culture and Evolution Brunel
University London, London, UK

Definition

An evolutionary theory of leader-follower relations that aims to explain why these relations can range from being “bad” (i.e., based on coercion) to “good” (i.e., based on mutually beneficial exchange).

Introduction

The service-for-prestige theory (Price and Van Vugt 2014, 2015) takes an evolutionary perspective on leader-follower relations in order to accomplish two main aims. The first aim is to explain why these relations can range from being “bad” and coercive (i.e., based on a leader’s ability to harm followers) to “good” and voluntary (i.e., based on a leader’s ability to benefit followers). The second aim is to propose that “good” leadership is governed by the logic of reciprocity, whereby leaders deliver public goods to followers in exchange for elevated social prestige. Both of these aspects of leader-follower relations are examined in more detail below.

What Are the Characteristics of “Bad” Versus “Good” Leadership, and Why Does Leadership Quality Vary So Widely?

People from a diverse variety of cultures tend to agree about what constitutes good leadership. The GLOBE survey (Den Hartog et al. 1999) measured preferences for leader traits across 61 cultures. The most consistently valued leader attributes were those which allow a leader to benefit followers via prosociality (e.g., trustworthiness, fairness) and ability (e.g., intelligence, competence). Similar findings are reported in a review of characteristics of successful leaders (Hogan and Kaiser 2005). These sources both suggest that followers prefer leaders who would make good exchange partners: people who have the skills that would enable them to benefit followers and who can be trusted to not be deceptive or exploitative. By the same token, these sources also suggest universal aversion to traits indicating that a leader would be a poor exchange partner (e.g., dominance, selfishness); leaders are generally reviled if they exploit their positions for their own benefit and at the expense of their followers (Tooby et al. 2006).

This spectrum of leadership styles, from bad (self-serving and exploitative) to good (trustworthy and productive of group benefits),

can be observed in modern environments. These leadership styles map on fairly well to the two kinds of social status that are commonly distinguished in behavioral science: dominance and prestige (Henrich and Gil-White 2001). The high status of bad leaders constitutes dominance, and leaders extract this status coercively, via their ability to harm followers. In contrast, the high status of good leaders constitutes prestige and is conferred voluntarily on leaders by followers, in exchange for the benefits that the leader provides. Humans obviously possess the psychological machinery necessary for engaging in both dominance-based and prestige-based leader-follower relations in modern environments, and service-for-prestige (Price and Van Vugt 2014, 2015) describes the kinds of hunter-gatherer environments of the evolutionary past that could have selected for this machinery.

Prestige-based leadership is common in the kinds of societies that were probably most typical of our evolutionary past: small (25–50 members) bands of nomadic hunter-gatherers. In contemporary examples of such societies, good leaders are described as skilled individuals who are voluntarily appreciated, respected, and followed by others, whereas bad leaders are group members who attempt to become too pushy, dominant, and coercive (Price and Van Vugt 2014, 2015). It's difficult to be a bad leader for very long among nomadic foragers because people will be both eager to get away from you and also relatively able to do so; in the fission-fusion societies of nomadic hunter-gatherers, it's relatively easy to leave one band and join another, and bands commonly break apart due to social conflict (Kelly 1995). Moreover, because these groups tend to be so small, organizing group members for collective action tends to be a relatively simple undertaking, and there is no great need for strong leadership in order to solve problems related to group coordination and free rider punishment. These two aspects of typical nomadic hunter-gatherer societies – the relative ease with which members can escape bad leaders and the reduced need for leaders to solve collective action problems –

combine to create an environment in which follower dependence on leaders is relatively low.

In other kinds of hunter-gatherer environments, however, the dependence of followers on leaders – and thus the power of leaders – can become much stronger. Indigenous peoples of the North American northwest coast lacked agriculture, but were nevertheless able to live in sedentary villages, because they settled close to rivers which allowed their main protein source – salmon – to deliver itself directly to them. These villages could grow to include hundreds of residents, much larger than nomadic hunter-gatherer bands, and so their collective action problems were more challenging to solve without strong leadership. Moreover, the sedentary nature of these settlements made fission-fusion social organization less feasible, and it therefore became harder to simply pack up and leave a leader who became too dominant. Increased dependence on leaders along the northwest coast created a niche for the emergence of leadership that was significantly more dominant than that seen among nomadic foragers; for example, although slavery is unknown among nomadic hunter-gatherers, it was common along the northwest coast (Kelly 1995).

According to service-for-prestige, the kinds of hunter-gatherer environments that selected for dominance-based and prestige-based leader-follower relations in the ancestral past are both represented in the modern world. The theory expects that in modern environments, dominance-based leadership will emerge most often in social environments more similar to northwest coast, that is, environments in which followers have low ability to reject or escape leaders (due to, e.g., poor exit options) and/or in larger social organizations in which strong leadership is required to solve collective action problems. In contrast, prestige-based leadership should more likely emerge in environments more similar to those of nomadic foragers, that is, environments in which followers have greater freedom to desert or depose leaders, and/or in smaller organizations in which coordination problems are relatively easily solved at a local level.

Leader-Follower Relations Are Perceived as Good When They Involve Voluntary, Mutually Beneficial, Service-for-Prestige Exchange

It was noted above that according to surveys of leadership preferences such as the cross-cultural GLOBE study, followers prefer leaders who would make good exchange partners: leaders who are willing and able to produce benefits for followers and who can be trusted to not abuse their power for their own narrow self-interest. Service-for-prestige (Price and Van Vugt 2014, 2015) suggests that people prefer leaders to be good exchange partners because in the evolutionary past, this preference would have enabled followers to engage benefit-generating leaders in mutually advantageous and therefore sustainable relationships.

How would this mutually beneficial exchange have played out in the evolutionary past? In hunter-gatherer environments, competent leadership benefits follower fitness by facilitating cooperation in activities such as warfare, big game hunting, forging political alliances, maintaining within-group order, and camp migrations. However, leadership roles often involve substantial costs for leaders, such as time and energy investments, stressful decision-making, and physical risk-taking. For these costs to pay off, and for leaders to be motivated to continue to lead, they must be compensated by some kinds of return benefits.

Accordingly, leaders do appear to be rewarded for the contributions they make. As high-prestige individuals, leaders are highly valued as friends, allies, and mates; and therefore social, material, and sexual resources tend to flow their way. Evidence that hunter-gatherer leaders receive relatively large shares of material and social resources can be challenging to collect, since this increased access may be observable only over the long term or under conditions of unusually great need such as sickness or sustained hunger. Nevertheless, respected leaders in small-scale societies have been observed to be rewarded over the

long term with social, political, and material support (Bird and Bliege Bird 2010; Gurven et al. 2000; Von Rueden et al. 2014). And when the focus is on reproductive rather than social and material resources, the rewards of leadership become relatively easy to observe. The high status of male leaders is attractive to women (Ellis 1992) as well as to parents who wish to form alliances with a leader by betrothing their daughter to him (Kelly 1995). In small-scale societies, higher status men are reported to have more wives and sexual partners, higher-fertility wives, and more surviving offspring (Chagnon 1979, 1988; Von Rueden et al. 2008, 2011).

Service-for-prestige suggests that just as leadership services were costly for leaders to provide, prestige allocations to leaders were costly for followers to make. Prestigious leaders have high power to benefit followers, so followers will invest time and resources to remain in good standing with them. Such investments may take the form of, for example, deferring to leader interests, sharing resources with the leader, taking pains to avoid harming the leader, and cooperating with a leader's directions instead of pursuing one's narrow self-interest (Price and Van Vugt 2014, 2015).

Prestige-based leader-follower relations constitute reciprocal exchange (Price 2003), then, because just as leaders voluntarily pay costs to deliver leadership services in exchange for prestige, followers voluntarily pay costs to deliver prestige in exchange for leadership services. However, because this prestige must often be allocated to the leader by a whole group of followers, it's a more complicated form of reciprocity than the dyadic reciprocal altruism first described by Trivers (1971). Although leader-follower reciprocity has aspects in common with dyadic reciprocal altruism, it also shares characteristics with *n*-person reciprocity (Tooby et al. 2006) and can be considered a form of collective action. And as in any collective action, a free rider's advantage (Olson 1965) will accrue to group members who accept the benefits of cooperation (in this case, a share of the services that the leader is motivated to provide, by virtue of

being compensated with prestige) but who do not pay contribution costs (in this case, the cost of allocating prestige to the leader). Service-for-prestige predicts that in order to neutralize this free rider's advantage, high contributors – that is, high allocators of prestige – will experience punitive sentiment towards those who fail to “pay respect” to leaders (Price et al. 2002). This phenomenon could be observed repeatedly in the notoriously violent rallies that occurred during Donald Trump's campaign to become the US Presidential nominee for the Republican Party, beginning in the latter months of 2015. A pattern developed at these rallies in which attendees who were perceived as not being sufficiently supportive of Trump would be humiliated and forced to leave, or even physically attacked, by other attendees who apparently considered themselves vociferous Trump supporters (Jacobs 2016).

Finally, it should be noted that the free rider problem described above applies only to prestige-based leadership scenarios, in which leaders are perceived by the group as being valued providers of public goods. In dominance-based leadership scenarios, in which the power of leaders is based on their ability to harm and intimidate followers, the logic of this collective action should essentially flip. If a leader is perceived as exploitative and parasitic rather than benefit-producing, then the collective action should focus not on maintaining leader motivation to lead but on removing the leader from power. In this flipped context, the role of selfless contributor would now be played by the member who undermines the leader's authority by rebelling against it and who thus risks attracting the leader's wrath. The free rider, meanwhile, would now be the member who continues to allocate status and thus lend support to the harmful leader. A real-world example of this sort of collective action would be Boston's famous 1773 “tea party,” initiated by rebellious colonists to outrageously undermine the authority of what they perceived to be an exploitative royal regime. From the perspective of tea party supporters, the rebels were heroic risk-takers, whereas the King's supporters were traitors who deserved to be publically humiliated (tared and feathered).

Conclusion

Leadership is not unique to humans and indeed is a feature of a vast variety of species, from bees to ravens to nonhuman primates (King et al. 2009). But whereas leader-follower interactions enable many species to solve coordination problems and share information, it is apparently only in humans that these interactions occur as reciprocal interactions, in which followers reward high-contributing leaders with allocations of social status. This context of reciprocity would have enabled human followers to allocate relatively large incentives (in the form of prestige) to their leaders and to thus embolden their leaders to make relatively costly and substantial leadership contributions. Thus, because they occurred as reciprocal exchanges, human leader-follower relations may have enabled the emergence of a kind of leadership that was more risk-seeking and self-sacrificial, more creative and committed, and generally higher quality than leadership in other species. Even if reciprocity-based leadership is indeed higher quality, however, this was apparently not enough to permit its evolution in nonhuman species. It seems that leader-follower reciprocity, like other forms of complex cooperation that can occur among nonkin (Tooby et al. 2006), is a behavior that the human brain is especially well adapted to achieve.

Definition

The way in which sexual behavior promotes the formation and maintenance of social relationships

Introduction

Sexual behavior is the means to reproductive success, the currency of evolution. Sexual behavior is promoted by sexual pleasure and orgasm; both of these, in behaviorist terms, are unconditioned stimuli that reinforce behavior (Fleischman 2016). Sexual pleasure and orgasm increase the positive associations of an individual towards a specific conspecific. In species that care for offspring, sexual pleasure facilitates close bonds and cooperation to care for offspring. In species where only one parent cares for offspring and in species that do not pair bond, sexual pleasure facilitates repeat copulations with a partner who is more likely to choose them compared with unfamiliar others. Pair-bonded species may develop longer-term preferences than more promiscuous species (Coria-Avila et al. 2016).

Biological Mechanisms of Bonding

Sexual behavior facilitates pair bonds through a few different mechanisms; these have mostly been extrapolated from work on nonhuman animals. Some of the major facilitators of sexual bonding are dopamine, oxytocin, and vasopressin. In species of rodents like rats and mice as well as the

monogamous prairie vole, it has been found that oxytocin and vasopressin are necessary for developing partner preferences (Young and Wang 2004). In humans, oxytocin and vasopressin are shown to be elevated during sex and orgasm in the blood of women and men, respectively (Young and Wang 2004). In women, oxytocin levels during sex have been shown to be associated with positive affect and thus also implicated in improved sexual bonding (Meston and Frohlich 2000). Dopamine is also implicated in the reward circuitry around sexual behavior and pair bonds and may be maintained by partner proximity showing reinforcing properties through previous sexual behavior.

Human Social Bonding Facilitated Through Sexual Behavior

Sexual behavior is inherently reinforcing because of its link to reproductive success, but this pleasure is also expected to reinforce other kinds of social bonds. In nonhuman primates, same-sex sexual behavior is not uncommon and much is thought to be affiliative (Vasey 1995). For example, female bonobos often have sex with one another and the bonds forged in this way allow them to form alliances to challenge larger stronger males (Vasey 1995). In humans, same-sex sexual behavior or homoerotic behavior may be used to promote affiliation. Progesterone, a hormone associated with affiliation, is associated with greater self-reported desire to engage with others of the same sex, and men who are primed with affiliation related words are more likely to report wanting to engage in homoerotic behavior, but especially when male subjects had higher salivary progesterone (Fleischman et al. 2015). Women are more likely to be bisexual than men and this may have evolved to promote alloparenting, sharing attention, and resources in caring for offspring (Kuhle and Radtke 2013). Similarly, men may have evolved the propensity for same sex behavior for the purposes of affiliation (Kirkpatrick 2000). The human propensity to engage sexually with those of the opposite sex, even when there is no possibility of reproduction, may also have the

function of promoting and maintaining adaptive social bonds (Fleischman 2016).

Conclusion

Sexual behavior has a number of neurobiological correlates that show evidence for design in the service of forming and maintaining social bonds such as oxytocin, vasopressin, and dopamine. Sexual behavior has rewarding properties that reinforce bonds between people of the opposite sex, often in the service of caring for offspring, but also can reinforce other kinds of social relationships.

Evolutionary theory predicts sex differences among humans, which may extend (or be amplified) after having children.

Introduction

This entry provides an evolutionary theoretical framework to help explain sex differences in mate preferences among human parents. Few data enable directly testing sex differences in mate preferences. However, various lines of inferential evidence, including patterns of sexual behavior, causes for divorce, and dating information on single parents, are presented.

Sex Differences After Having Children

The evolutionary foundation of sex differences in mate preferences draws upon theoretical insight into the evolution of sex differences in reproductive effort more broadly (see ► [Sex Differences in Human Mate Preferences](#) (Buss, 1989); ► [Sex Differences in Parenting and Parental Investment](#)). Sex differences have been variably linked to gamete size (see ► [Sex Differences in Same-Sex Aggression](#); ► [Gamete Size](#)), relative parental investment, potential reproductive rate, and actual reproductive rate. If females typically have a lower actual reproductive rate than males, this observation helps account for sex differences in mate preferences; for example, males may have lower minimal standards in a mate given relative reproductive constraints.

Sex differences in mate preferences that preexist having children may persist after having children. However, there is reason to theorize that having children may also alter the nature of sex differences in mate preferences. Reproductive effort can be portioned into mating and parenting effort. Multiple lines of evidence from various societies indicate that women allocate a relatively higher proportion of their reproductive effort to parenting effort compared to men. After having young children, women may expend considerable time and energy nursing their offspring and tend to engage in higher rates of direct child care than fathers. For such reasons, sex differences in actual reproductive rates may be magnified, contributing in turn to life history stage-specific sex differences in mate preferences. For example, mothers may place a greater premium on a partner's ability to

provide the resources she and her child need than she did before having children, compared with fathers' preferences (see Weeks-Shackelford et al. 2007).

There are few data directly addressing sex differences in human mate preferences after having children. In a recent study of 747 single parents drawn from a demographically representative US sample of adult singles, several sex differences in mate preferences emerged among parents (Gray et al. 2016). Mothers were more apt than fathers to take seriously their children's opinion of their dating partner, while fathers were more likely than mothers to allow their children to set them up on dates. In a related national US sample, single fathers reported more often thinking about sex, having sex, having more sexual partners the past 12 months actively seeking a new partner, and going on more dates compared with single mothers (Gray et al. 2015a). The remainder of this entry draws largely upon inferential studies to help shed light on sex differences in mate preferences among parents.

Classic research on sex differences in mate preferences showed that women tended to value cues of male status and resources more than did men, whereas men tended to value cues of a partner's attractiveness more than did women. There is good reason to believe these sex differences persist, if not increase in magnitude, after having children. Sources of marital conflict and divorce highlight sex differences in the causes of relationship challenges. These show in Western and cross-cultural records that men are more likely than women to specify infertility and infidelity as causes of divorce; these observations fit with a view that men's mate preferences are attuned to cues of fertility and fidelity. Conversely, women's grounds for divorce more often cite physical abuse and inadequate resource provisioning, consistent with mate preferences that value relative safety and support in helping raise her offspring.

Research suggests sex differences in sexual desire and partner variety after having children (Gray and Garcia 2013). These observations are related to mate preferences – in whether desiring to mate at all and with how many partners.

Importantly, these aspects of sexuality are likely magnified in later pregnancy and in early stages after having children relative to pre-parental or later-parental stages. A way to conceptualize these enhanced sex differences begins with the recognition that women's reproductive effort privileges current over future reproduction during pregnancy and intensive postpartum parental care (Escasa-Dorne et al. 2013). Time and energy devoted to caring for a newborn draws away from maintaining psychological and physiological support for conceiving the next child. These life history shifts are orchestrated in part by changes in maternal hormone levels. Mothers' testosterone and estradiol levels decrease after birth, two hormones important in sexual activity. Conversely, elevated oxytocin and prolactin levels, which increase in women after birth to aid in lactation and direct maternal care, may have consequences for partnership behaviors (i.e., enhancing an infant bond at expense to that with a mate).

While becoming a father can impact men's psychology, physiology, and overall reproductive effort, those relative impacts are less than among mothers. Consistent with such views, mothers of young children tend to exhibit lower sexual desire and more pain during sex compared to fathers of young children. In several societies such as St. Louis in the mid-twentieth century and among the Ngandu farmers of Central Africa, the increased sexual conflict over desire for sex has been reported to lead to elevated risk of fathers seeking extra-pair partners. In a study of some 3410 Jamaican fathers of newborns, about half of men reported no sex the previous week. Yet approximately 30 % of fathers reported multiple sexual partners the previous 12 months, with younger men, men in visiting relationships, and men in lower quality relationships those more likely to report more sexual partners (Gray et al. 2015b). Relatedly, some mothers of infants in Manila, the Philippines, reported engaging in sex with their husband in what amounts to a relationship maintenance strategy – having sex to appease a valued partner rather than driven by one's own inner desire (Escasa-Dorne 2015).

Most of human reproduction ancestrally and today occurs within long-term partnerships that

are often codified by marriage (Gray and Garcia 2013). The same classic studies of cross-cultural mate preferences that showed some evidence of sex differences also showed considerable sex similarity: the most preferred traits indicated the importance of character and compatibility, consistent with a preference for cues suggesting success in maintaining a long-term partnership. Continued maintenance of a long-term partnership may be beneficial after having children, given the considerable time and resources humans expend on their offspring. Nonetheless, the death of a partner or dissolution of a relationship regularly leaves many parents single. Hunter-gatherer demographic studies suggest that divorces and re-partnering after having had children are regular occurrences. Yet apart from the US study cited above, what sex differences might be expected in the mate preferences of single parents?

Inferential insight suggests single mothers may be more attuned to partner cues indicative of safety for herself and her offspring. Research by Martin Daly and Margo Wilson, among others, showed that young children face elevated risk of physical abuse and death among step-figures, particularly stepfathers. A public health campaign deployed in parts of the USA entitled, "Choose Your Partner Carefully" focuses on single mothers rather than single fathers for this reason. Mothers may prefer cues of a potential partner's kindness (e.g., in faces, voices, and personality), perhaps to invest in her and her offspring but also to do her and her offspring less harm (Escasa-Dorne et al. 2013; Weeks-Shackelford et al. 2007). Relatedly, among Hadza hunter-gatherers of Tanzania, breastfeeding women preferred high-pitched male voices while women who were not breastfeeding preferred low-pitched voices (Apicella and Feinberg 2009). Several studies from the UK, the USA, and the Philippines focused on mothers' evaluations of male faces have shown that mothers of young children exhibited preferences for feminine male faces (Cobey et al. 2014; Escasa-Dorne et al. 2016). Moreover, parenting effort may influence women's preferences for a healthy partner, particularly in high pathogen load areas. For example, pregnant and breastfeeding Hadza women had an increased preference for

symmetrical male faces compared to non-pregnant and non-nursing women (Little et al. 2007).

All else being equal, single parents may hold lower mate value on the mating market. A parent's child can take away time spent between partners, and children may require resources and time that a prospective partner may not wish to share. In the same US singles study previously noted, there was no sex difference in the interest of single parents in dating other single parents (Gray et al. 2016). Yet single parents may collectively express less discerning mate preferences, consistent with a lower mate value attendant to having children. Relatedly, it may benefit a single parent to prefer a partnership with someone who has a lower self-perceived mate value or lower mate quality, as it may free them from having to continuously maintain the relationship (i.e., mate guarding) allowing a parent to direct her attention to parenting. It also bears underscoring that many single parents weigh their children's presence and views in parental dating and mating behavior.

Individual mate preferences are contingent on individual (e.g., mate value), relationship (e.g., relative mate values between partners), and wider social contextual (e.g., availability of alternative partners) factors. This means that the nature of sex differences in parents' mate preferences is also contingent on these same considerations. Just as variation in the social ecology of physical threats may impact how desirable a man's formidability or other cues indicative of protective capacity, so the magnitude of parents' sex differences in mate preferences for cues of protective abilities may also vary. Future work might seek to quantify the relevance of variable male provisioning, other features of a sexual division of labor, parental manipulation, and single parent child custodial time, among other factors, in impacting sex differences in parents' mate preferences.

Conclusion

Few studies directly address sex differences in mate preferences after having children. However, multiple inferential lines of evidence such as

patterns in sexual behavior, causes of divorce, and cross-cultural data on mothers' mate preferences point to the continuation if not amplification of sex differences in mate preferences after having children.

Sex Differences for Pursuing

Hannah Sheehan
University of Bristol, Bristol, UK

Synonyms

Affair; Cheating; Extra-dyadic interaction; Extra-dyadic sex; Extra-pair sex; Infidelity; Unfaithful behavior

Definition

Extra-pair mating is a promiscuous mating strategy adopted by individuals in a monogamous relationship. It involves one individual engaging in sexual relations outside of the exclusive pair.

Introduction

The visibility of extra-dyadic interactions among high-profile celebrities in the media suggests a preoccupation with infidelity among the general public. Monogamy in intimate relationships is a traditional norm, and many individuals consider unfaithful behavior as intrinsically wrong. Despite these common beliefs, a meta-analysis conducted by Tafoya and Spitzberg (2007) suggests 34 % of males and 24 % of females have engaged in sexual relations outside of their marriage. Although infidelity is deemed an atypical behavior, it appears many people have, and will continue to, engage in extra-pair sex. This is concerning as the consequences of infidelity are often tragic. Daly and Wilson (1988) found an awareness of a partner's infidelity can elicit dangerous behaviors such as physical violence and even murder. This entry will explore sex differences in the pursuit of extra-pair mates by reviewing empirical and theoretical research.

Why Do We Engage in Infidelity?

A consistent finding in previous research is that of a sex difference, males appear to engage in infidelity more often than women cross-culturally. A considerable amount of research demonstrates men have stronger urges to engage in infidelity than women and are more likely to engage in sexual infidelity (Martins et al. 2016). In addition, men are likely to engage in more cases of infidelity than women (Brand et al. 2007). Research proposes the consistent sex difference can be explained via the application of evolutionary theory (Buss and Schmitt 1993), specifically, parental investment theory (PIT; Trivers 1972). PIT is grounded on the notion that women and men have different levels of obligatory minimal investment to their children. Women are obliged to invest at least 12 months of time and energy into pregnancy and lactation; in contrast, males only need to invest in sex if they wish. This difference in parental investment means men and women will benefit from different mating strategies. PIT proposes the sex which invests the least (males), can

benefit reproductively by adopting a quantity-over-quality strategy. PIT suggests males are likely to engage in short-term mating with multiple partners. This idea is consistent with the aforementioned research (e.g. Martins et al. 2016). For females, however, every child requires at least a 9-month internal gestation period. Therefore, females are more likely to adopt a quality-over-quantity strategy. Reproductive fitness among males is highly variable and, due to a minimal level of parental investment, the number of children a male can have is effectively unlimited. Reproductive fitness among females is considerably less variable due to the restraint of parental investment. A married woman could not increase her direct reproductive fitness by engaging in infidelity unless her partner was infertile or uninterested in sex (Greiling and Buss 2000).

However, women do engage in infidelity. Obvious clues to an evolutionary history of female infidelity derive from research concerning male sexual jealousy. Male sexual jealousy is a vicious reaction induced when males suspect sexual infidelity and often leads to physical abuse and occasionally homicide (Daly and Wilson 1988). Due to internal fertilization, women are 100 % certain their offspring are their own. However, men can never be completely sure. Research suggests male sexual jealousy is initiated by cues of infidelity (Greiling and Buss 2000) as extra-dyadic sex compromises paternal certainty. If females always remained in monogamous partnerships, why would males have evolved a psychology of sexual jealousy (Greiling and Buss 2000)? Behavioral evidence of female infidelity also suggests women do not always pursue a monogamous long-term mating strategy. Extra-marital sexual liaisons have been documented in both Western societies and in more primitive communities, such as the Yanomamo of Venezuela (Greiling and Buss 2000).

The reason for ancestral male infidelity is obvious; there is a direct reproductive benefit. Men who have sex with multiple partners will have greater reproductive success compared to males who only have sex with one female. Buss (2003) reported extra-dyadic sex comprises 20 % of males' sexual activity between ages 16 to 35 and

steadily increases to 35 % between ages 46 to 50. It is likely that this increase in extra-dyadic sex corresponds to a decrease in their partner's attractiveness and fertility (Buss 2003). For males who engage in sexual infidelity, casual sex becomes increasingly significant with age at the cost of sex with their wives. The benefits of female infidelity are less apparent and may have been masked by the noticeable costs of extra-pair mating. Females who engage in infidelity are confronted with risks of catching a sexually transmitted disease, a damaged reputation as a long-term partner, a loss of resources from their current partner (Buss and Schmitt 1993), and are at risk of suffering the effects of male sexual jealousy (Daly and Wilson 1988). What benefits could possibly outweigh all these costs?

Symons (1979) proposed a resource acquisition hypothesis for female infidelity. Symons suggested ancestral females may have benefited from infidelity by exchanging sex for goods, such as meat or jewelry. Research has shown women do obtain resources for sex. In many communities males are required to bring gifts to their mistresses and women may decline sex if these gifts are absent (Greiling and Buss 2000). Buss and Schmitt (1993) found further evidence supporting the resource acquisition hypothesis by assessing desires in the context of long- and short-term mates. They demonstrated females valued resource acquisition significantly more in a short-term context. Men who upheld an expensive lifestyle and showered women with gifts were seen as more desirable in a short-term context than a long-term context.

A further potential benefit of female infidelity is the acquisition of "good genes" (Symons 1979). Women may engage in extra-dyadic sex to secure genes that are superior to those of her current partner. A highly attractive man is often willing to have sex with a less desirable woman if she places no burden of commitment (Buss 2003). A less desirable female may be able to obtain reliable resources from her current partner and superior genes from an affair partner. Women who obtain "better genes" could increase the reproductive success of her children, thus increasing her own inclusive fitness. For example, if a

woman has sex with a highly attractive man, it is likely that her sons will be highly attractive too. Highly attractive sons may spark more interest from choosy females, resulting in more grandchildren. Gangestad and Thornhill (1997) investigated the good gene hypothesis by asking women about qualities they seek in extra-pair mates. They examined numerous variables including age, income, and sexual experience. The researchers also measured two characteristics of “superior genes” – physical symmetry and attractiveness. The results showed women are more likely to choose symmetrical men as affair partners than long-term mates. Symmetrical men are usually muscular, healthy, and intelligent in comparison to their nonsymmetrical counterparts (Gangestad and Thornhill 1997). However, physically symmetrical men have been shown to be more adulterous and dishonest to partners (Gangestad and Thornhill 1997) and so would not be suitable as long-term mates.

In addition to acquiring “good genes,” obtaining a different mate is another significant benefit of female infidelity. The mate switching hypothesis (Buss 2003) suggests women may engage in affairs to leave unhappy relationships, often by encouraging her long-term partner to break up with them. Females may also engage in infidelity as a practice run with another mate to assess if they are compatible. There is an abundance of empirical evidence supporting the mate switching hypothesis. Many studies have found women who engage in infidelity are significantly less happy with their marriages both emotionally and sexually, compared to their non-adulterous counterparts (Brand et al. 2007). In addition, strength and frequency of affairs are significantly related to the level of dissatisfaction women experience in their long-term relationship (Tsapelas et al. 2011).

Greiling and Buss (2000) conducted four studies investigating women’s sexual strategies. The studies assessed different hypotheses concerning the benefits women may gain from engaging in extra-pair mating and the situations in which they do so. Strong support across all four studies was found for the mate switching hypothesis and the resource acquisition hypothesis. The results

indicated that women believed they would find a more desirable mate by engaging in infidelity. In addition, study three found the situations most likely to promote infidelity among females were feeling that she can find a more compatible partner and meeting someone who seems more interested in her. These findings provide strong support for the mate switching hypothesis. Resource acquisition also emerged from the research as a conceivable adaptive function of infidelity. Study one showed women often acquire money, free dinners, and jewelry after engaging in extra-pair sex. Study four also found females who engage in infidelity perceived resource acquisition as highly beneficial. Recent research conducted by Brand et al. (2007) further supports the mate switching hypothesis. They found women were significantly more likely than men to cheat on their partner because they were unhappy with their current relationship.

The research discussed in this entry so far suggests that women not only benefit from long-term mating but also reap rewards from engaging in extra-pair liaisons. The studies provide a glimpse into why women may risk the dangerous consequences of infidelity and the situations in which infidelity may be profitable.

Is the Gap Closing?

The majority of infidelity research has focused on sexual intercourse (Brand et al. 2007); however, studies are now exploring nonsexual infidelity. When definitions of infidelity include kissing or dating, sex differences appear to diminish. Using both student and community samples, Brand et al. (2007) found men were not more likely to engage in infidelity than women; in actuality, women reported a higher incidence of infidelity than men. The authors suggest sex differences apparent in past research may be outdated and inaccurate. Tsapelas et al. (2011) propose the decreasing sex difference may be attributed to socioeconomic changes – females are becoming increasingly independent both in the workplace and within the home. Although recent research suggests the amount of women and men who

commit infidelity is similar, studies have reported that men engage in more episodes of infidelity than women (Brand et al. 2007). Martins et al. (2016) investigated rates of online infidelity such as cybersex and “sexting” and found that although rates of infidelity are converging, men still report higher episodes of infidelity. These results are consistent with PIT (Trivers 1972); males may be adopting a quantity-over-quality strategy (Brand et al. 2007).

Limitations

Considering the sensitive nature of infidelity, research findings should be interpreted with some caution. Many of the empirical studies cited previously rely on self-report measures. Due to the negative connotations associated with extra-dyadic involvement, participants may not be entirely truthful and present answers which are more socially desirable (Tsapelas et al. 2011). It is also important to be aware that some of the studies are correlational meaning causation cannot be assumed. There are also methodological problems within infidelity research. Authors often define infidelity differently; some studies include flirting, kissing, and cybersex in their definition of infidelity, while others only define infidelity as extra-pair sex (Brand et al. 2007). This may have skewed results. Tsapelas et al. (2011) suggest future research could consider gathering data from the individual and their affair partner; this may increase the understanding of infidelity. In addition, longitudinal studies may provide accurate information about relationships and the reasons why infidelity occurs.

Conclusion

Films, books, and television shows often portray women as faithful partners, while men are depicted as having animalistic urges, leading them to cheat on their wives. Past research proposed men were considerably more unfaithful; however, recent research has suggested this is not the case. Although it seems the incidences of

men and women engaging in extra-pair sex are becoming increasingly similar, the reasons for pursuing an extra-pair mate remain very different. Men engaging in infidelity are likely to be “spreading the seed” and may be seeking opportunities to have sex with a variety of women. However, it seems women engage in affairs when they are truly unhappy in their current relationship. Infidelity may give females an opportunity to find someone who is more compatible. Although this entry has explored why the pursuit of extra-pair sex may be beneficial, it is important to remember it is not inevitable.

Sex Differences in Ability to Assess Fighting Ability

David Johnson

Michigan State University, East Lansing, MI, USA

Synonyms

[Formidability assessment](#)

Definition

Empirical evidence supports the conclusion that men and women are equally skilled at assessing fighting ability in men.

Introduction

Humans show a large degree of sexual dimorphism in upper body strength. Because of the tight relationship between upper body strength and fighting ability, men are much better equipped to engage in physical aggression than women. Historical records of human activity support the idea that widespread intrasexual (same-sex) competition was a common occurrence between human males. This historical pattern suggests that any cognitive program that developed through natural selection might be especially tuned to assess cues to fighting ability in men.

Empirical Evidence

Evidence in support of this idea comes from work by Sell and colleagues (2009, 2010). Strength ratings of men judged from facial photos correlate more strongly with upper body strength ($r = .39$) than strength ratings for women ($r = .21$). Similarly, strength ratings of men judged from voice recordings correlate more strongly with actual upper body strength ($r = .51$) than strength ratings for women ($r = .26$). However, ratings of the body (excluding the face) are less supportive; ratings of men ($r = .57$) only correlate slightly more strongly with upper body strength than women ($r = .51$). This small difference is surprising given that men in those studies were photographed shirtless, whereas women were photographed wearing shirts. If anything this should exaggerate assessment differences, as it is more difficult to see women's musculature.

Another problem with the conclusion that humans are better equipped to assess male strength is due to the methodology of strength assessment in men and women. Typically, these studies take strength measurements as well as pictures or voice recordings of various men and women. Participants are then asked to rate the individuals in the pictures or recordings on their strength and/or fighting ability as compared to the population of men or women. However, this method confounds the issue of mean level sex differences in strength with differences in the within-sex variability of strength. Not only are men stronger than women, but there is more variability in strength within men than there is with women (Lassek and Gaulin 2009). This creates a situation where the cognitive program that assesses upper body strength must make finer grained distinctions between women than men. Thus, it is possible that the attenuated relationship between rated and measured strength for women may simply be due to the restricted range of female strength relative to male strength.

Finally, there is little evidence of sex differences in rater accuracy of upper body strength and fighting ability. Untrained men and women are equally skilled at assessing the winners of mixed martial arts competitions (Little et al. 2015) and

assessing upper body strength from the voice. There is some evidence that men might be better able to assess women's strength from photographs (relative to women), but these differences are generally small and inconsistent. This reflects the fact that being able to predict the victor of physical conflict was important for both men and women throughout evolutionary history, even though women were historically less likely to engage in and be victims of aggression.

Conclusion

Future research could address the issue of restricted range by using a forced choice paradigm where raters see pictures of two same-sex individuals and must assess which person is stronger. Individuals could be paired so that they were relatively similar in strength, eliminating the issue of within-sex variability differences. If humans are better equipped to assess male strength than female strength, then they should be better able to accurately assess what person is stronger in male pairs than in female pairs. Thus, it remains unclear whether sex differences in strength assessment result from the cognitive program being better "tuned" for men or just a methodological artifact.

Sex Differences in Aggression

C. Tevlin

Florida State University, Tallahassee, FL, USA

Synonyms

Assault; Hostility; Physical aggression; Rape; Social aggression; Violence

Definition

A forceful, hostile, or violent behavior or attitude towards another, especially when intended to dominate or master.

Introduction

The relationship between sex and aggression is now undeniable, with countless studies revealing

males are more aggressive than females. Empirical research consistently finds that males are more aggressive than females in virtually every society across time and place (e.g., see Junger-Tas et al. 2004). Furthermore, gender disparities in offending are greatest for violent and serious property crimes such as murder, robbery, and burglary. While the correlation between gender and crime is robust, the theoretical explanation for why this gender gap in offending exists continues to be hotly debated in the field of criminology. Criminological research attempting to explain the nexus between sex and aggression has mainly focused on sociological explanations, but a growing line of research has revealed that biological and genetic roles may also play a vital part in explaining gender disparities in antisocial behavior.

Gender-Gap in Offending

Sex is generally recognized as one of the most robust correlates of crime within the field of criminology, wherein males are significantly more likely to exhibit antisocial behaviors than are females. These gender disparities comprise what is known as the gender gap in offending (Moffitt et al. 2001) and have been consistently found in research examining male-female differences in aggression. Empirical research demonstrates that the gender gap exists in virtually every culture, as well as across various time periods and places (e.g., see Junger-Tas et al. 2004). Moreover, sex differences in offending are more pronounced when looking at more serious and violent crimes. Official records within the U.S. reveal that adult males were responsible for approximately 81% of all violent crime arrests made within 2009, with males accounting for nearly 88% of arrests for robbery and 90% of the arrests for murder (e.g., see U.S. Department of Justice, Federal Bureau of Investigation 2009). These numbers are also reflected in juvenile statistics, with several self-report studies reporting that 80% of the youth who report carrying a weapon are male (Archer 2004). Consistent with these findings, results from observational studies and parental reports have

demonstrated that sex differences in physical aggression emerge early in the life course, even prior to the preschool years (Archer 2004; Tremblay 2006).

Although female violence is a rare phenomenon, some females are indeed found guilty of committing violent offenses. Compared to males, however, females tend to begin and end their violent careers earlier in the life course and are also far less likely to repeat their violent offenses (Moffitt et al. 2001). According to a longitudinal study conducted by Moffitt et al. (2001), less than 1 in 100 females in a cohort are on the path to becoming a life-course persistent offender when held to the same standards as their male counterparts (Moffitt et al. 2001).

Even though empirical evidence demonstrates a close relationship between sex and aggression, some scholars have argued that the gender gap in offending is not as clear-cut as it may seem. For instance, some researchers have found that gender ratios appear to be greater in studies utilizing official statistics such as arrest records versus studies employing data garnered from self-report surveys (Moffitt et al. 2001). This may be due to a number of possibilities, some which may not be related to actual offending behavior. That is, variation in the gender gap may be due to police bias in determining who is arrested, with females often being arrested less than men, or it may be because the majority of crimes committed by females tend to be minor, and therefore go unnoticed by the police. Despite females reporting higher levels of antisocial and criminal behavior in self-report surveys than is reflected in official reports, males remain the dominant sex in nearly every crime category, especially those reflecting serious and violent crimes (Moffitt et al. 2001).

Researchers have also suggested that the gender gap varies based upon the type of crime or aggression measured. For example, sex disparities tend to shrink when examining minor crimes such as drug and alcohol offenses and females even exceed the number of male arrests in two categories: prostitution (70% of all arrests) and truancy (55% of all arrests) (U.S. Department of Justice 2009). Perhaps even more shocking, data has revealed that in regards to partner abuse, females

match or even exceed the physically violent behavior of males (Moffitt et al. 2001). Furthermore, some scholars claim that females are not necessarily less aggressive than men but instead exert a different form of aggression. That is, while males are typically physically aggressive, females tend to exhibit greater levels of indirect, or relational, aggression. These scholars argue that the choice of aggression diverges between sexes due to their biological differences that are continually reinforced by social norms. Females choose to utilize indirect forms of aggression because they are physically weaker than males and therefore are forced to find an alternative way to achieve their desired results other than using physical aggression. Therefore, females should not be considered less hostile than males due to the fact that hostility is subjective based upon which sex is being studied. In other words, these scholars suggest that the differences most studies find in regards to male-female aggression are due to the focus on physical aggression, which is primarily used by males and typically avoided by females. Empirical evidence seems to contradict these claims, however. For example, a meta-analysis conducted by Archer (2004) found that although females were more likely to exhibit indirect aggression, the difference between sexes was extremely small. Results for physical aggression were in line with previous research, wherein males were significantly more likely to be implicated than females. A more recent meta-analysis conducted by Card et al. (2008) mirrored these results, finding that gender differences were greatest for direct aggression – with results favoring males – while gender differences in indirect aggression were nonsignificant.

Taking this evidence into account, gender disparities in antisocial behavior appear to be robust, with results consistently finding males to be more aggressive than females regardless of how the construct is measured. Although the correlation between sex and aggression is robust within the empirical literature, biological sex cannot in itself be considered a “cause” of crime. That is, simply being male does not cause an individual to become aggressive or lead them to commit an offense. Therefore, the reason why the gender gap in offending exists remains a matter of

significant debate. Criminologists researching the gender gap have traditionally explored which sociological variables may be responsible for the observed sex differences in aggression. A separate line of research, however, has begun to demonstrate the role of biological and genetic variables in the etiology of antisocial behavior and suggests that they may play a critical role in the developmental differences of male-female antisocial behavior.

Social Influences on Offending

Historically, criminological theory and research has focused on the environmental and social factors that influence aggression. This body of research emphasizes the role of cultural and community influences, peer influences, and parental management technique.

Cultural and Community Influences

One line of this research examines whether cultural influences and community influences, such as social-structural processes, traditional male and female social roles, school, and neighborhood contexts, are responsible for the observed sex disparities in aggression. Social-structural processes are often explored in the quest to find the variables responsible for the observed gender disparities in aggression. Theories taking this stand (i.e., social role theory, power control theory) argue that in patriarchal societies, males and females are socialized based upon the roles found in traditional division of labor in which males are employed outside the house while females’ duties take place within the home. Therefore, societal norms lead parents to exert more control over their daughters than their sons in an effort to reproduce the gender division between family and work. As a result, females are socialized to avoid responding to situations with aggression and are taught to empathize and care for others, while males are taught that risk-taking and aggression are masculine qualities and are socialized to use aggression as an appropriate response to some social situations (Archer 2004). Data tends to support this view; that is,

males are more likely to commit assault against an acquaintance or stranger than are females and, when females are arrested for a violent offense, the victim is typically a family member (Moffitt et al. 2001).

Empirical evidence investigating the influence of social-structural processes that occur within the family on aggression has been mixed. While some studies have found that gender and delinquency were related to parents' relative authority in the workplace, other studies have found that gender differences in several forms of delinquency occur regardless of the social-structure of the youth's family (Archer 2004).

In addition to cultural influences, criminologists have found that community factors such as school may play an important role in the etiology of aggressive behavior. Attachment to school and teachers, enthusiasm for learning, and high academic performance have been implicated as protective factors against the etiology of delinquent behavior for both sexes (Fagan 2015). Empirical studies have consistently revealed that males, however, not only have a higher risk of experiencing academic difficulties, they are also more affected by school problems than are females. For example, a meta-analysis conducted by Maguin and Loeber (1996) found that poor academic performance not only predicted delinquency, but that this association was stronger for males than for females. Furthermore, a growing body of research has demonstrated that poor verbal skills are significantly predictive of antisocial behavior both in the early school years and later in life, and that males exhibit language deficits at a higher rate than females.

While some empirical studies find evidence to support the theory that difficulties in academia may have a greater effect on delinquency for males than females, school variables fail to account for a large portion of the variance between sex and aggression. Even when utilizing multivariate statistical models able to control for various academic factors, the effect of sex on aggression typically remains statistically significant (Junger-Tas et al. 2004; Yun et al. 2014). For example, a recent multivariate analysis found that while lower levels of academic performance were

predictive of a greater number of arrests, sex remained a statistically significant predictor of arrests as well (Yun et al. 2014). Males reported more arrests than females regardless of academic performance, suggesting that other factors may be important in explaining sex differences in criminal activity. This study also incorporated models which included two well-documented criminogenic risk factors: low levels of self-control and prior delinquency. In these multivariate models, the effects of gender were somewhat attenuated, yet remained statistically significant in the prediction of number of arrests (Yun et al. 2014).

Researchers have also explored whether or not neighborhood characteristics, such as economic status and availability of social control sources, influence the etiology of sex differences in offending. It is theorized that because boys receive less monitoring by parents than females, they are likely to spend a greater amount of time in the neighborhood participating in both structured and unstructured activity. Therefore, males are exposed to a greater number of neighborhood risk and protective factors, suggesting that neighborhood characteristics may be more influential for males than females.

Empirical studies investigating the influence of neighborhood factors on the variation between male and female offending behavior are limited. Evidence from these studies provides mixed support for the theory that neighborhood characteristics cause sex differences in antisocial behavior. For example, a handful of studies have found neighborhood characteristics such as economic disadvantage, informal social control, and collective efficacy have equal effects on both sexes. In contrast, a study conducted by Zimmerman and Messner (2010) found that gender differences in violence and offending reduced as neighborhood disadvantage increased, with sex differences becoming nonsignificant in the most disadvantaged neighborhoods. These results indicate that economic disadvantage can account for the entire gender gap in offending. Furthermore, Fagan and Wright (2012) found neighborhood characteristics may actually be more influential for females than for males. Specifically, an increase in

collective efficacy was significantly associated with an increase in the number of delinquent acts reported for females but not males, and concentrated disadvantage was related to significantly lower violent acts for females but not males. Collective efficacy and concentrated disadvantage were not able to significantly predict the likelihood that either sex would participate in general or violent crime, however (Fagan and Wright 2012). Findings from this body of research highlight the need for future research assessing the relationship between neighborhood factors and the gender gap.

Peer Influences

One of the more prominent theories in criminology, social learning theory, claims that cultural values are transmitted through formal and informal systems of social control (i.e., school, parents, peers) and, therefore, aggressive behavior is learned and maintained throughout an individual's development by these sources. In terms of peers, social learning theory claims that an increase in exposure to delinquent peers increases an individual's chance to learn delinquent definitions and in turn increases that individual's acceptance of aggressive values and subsequent participation in delinquency. Researchers have sought to determine whether differences in delinquent peer associations may in fact explain the gender-crime association.

Specifically, these studies investigate whether gender has an effect on an individual's exposure to delinquent peers and definitions as well as what the effect this delinquent exposure has on each sex. Studies typically find that males do have more delinquent associations than females (Moffitt et al. 2001; Piquero et al. 2005; Zimmerman and Messner 2010). For example, Piquero et al. (2005) found that delinquent peer associations are a better predictor of male delinquency than female delinquency, while other studies have demonstrated that both sexes are equally affected by delinquent associations and definitions (Moffitt et al. 2001; Yun et al. 2014). Furthermore, a study conducted by Haynie et al. (2007) revealed that females' contact with delinquent males increased female violence, but male

contact with female delinquents had no effect, suggesting that the relationship between delinquent peer contact and aggression is more complicated than it may appear. These mixed results indicate that while delinquent peer variables might partially explain the correlation between sex and aggression, further research is required in order to fully understand the relationship.

One methodological problem that plagues the majority of delinquent peer research is that these studies rarely account for the possibility of self-selection effects (Fagan 2015). That is, it may not be that the bonds with delinquent friends cause an individual to commit crime, but that participating in criminal acts leads one to seek out delinquent friends. Because males are more likely to be involved in delinquency than females, they are also more likely to come across other delinquents and bond with them based upon their shared interest in offending (Fagan 2015). This line of reasoning suggests that although there appears to be a relationship between delinquent peers and aggression, other variables (such as genetics) likely play a critical role in this relationship. Therefore, the likelihood that peer variables are responsible for the variation in male and female offending is small.

Family Influences

Parental socialization factors are perhaps the most studied variables in the quest to determine why some individuals commit crime. Parents can influence their child's antisocial behavior in a multitude of ways. Theoretical explanations posit that parents supervise and socialize males and females differently, thereby leading each sex to develop a different propensity toward antisocial behavior. For instance, criminologists state that parents can thwart the etiology of delinquency for both males and females by closely supervising their children, recognizing deviant behavior when it occurs, and punishing that behavior in an appropriate manner. Parents tend to monitor daughters more closely than sons, however, therefore consistently discouraging antisocial behavior among females while simultaneously allowing males greater opportunity to misbehave and escape detection.

Empirical studies investigating the relationship between gender disparities in parental management techniques and their subsequent effect on delinquency provide mixed evidence. While some evidence demonstrates that daughters experience a greater amount of parental monitoring (Junger-Tas et al. 2004), other studies have contradicted these results, finding similar levels of parental monitoring and discipline between the sexes (Lytton and Romney 1991). Moreover, parental socialization factors tend to have comparable effects on delinquency for males and females.

Another consequence of the differential ways parents socialize their sons and daughters is that females seem to develop stronger social bonds with their family members than males. As a result, the influence of parental management techniques such as supervision and discipline may be greater for females than males, thereby reducing future female delinquency. Empirical evidence investigating this claim is also mixed, however. A number of studies have found that girls have a greater attachment to their parents than males (Junger-Tas et al. 2004), and that this attachment reduced violence for females but not males. However, studies have also found that parent-child attachment also reduced aggression for males as well. The claim that increased parenting practices are the result of greater social bonds between females and their parents has also received mixed empirical support. For example, while some studies have found that the effect of parental socialization has a stronger influence on antisocial behavior for females than males, others have demonstrated that parental socialization factors have a greater effect for males (Fagan 2015). Still other studies have revealed that the influence on the majority of parental socialization factors on aggression have an equal influence for males and females (Moffitt et al. 2001).

In addition to the variation in parental management techniques, parents frequently socialize girls to be aware of others' feelings and teach them how to empathize with others. As a result, scholars have theorized that females typically have a greater capacity for empathy, which has been demonstrated to have a strong inhibitory effect

on criminal involvement. While empirical evidence has found that females exhibit higher levels of empathy at a greater rate than males, the evidence also demonstrates that empathy's protective factors appear to reduce offending for both sexes (Broidy et al. 2003). The link between parental socialization factors and the development of empathy is unclear; however, empirical evidence from biological studies have found that other factors, such as neurological differences, account for the majority of variance displayed in male and female emotions, including empathy (Tibbetts 2013).

Although the majority of criminologists favor parental socialization as the main factor behind the differences in male and female aggression, empirical evidence suggests that this relationship may not be as strong as was once thought. To start, although parental socialization factors are often found to be statistically significant in the relationship with criminality, these coefficients tend to be relatively small and are often rendered nonsignificant when genetic factors are also included in the statistical models (Beaver and Nedelec 2015). Therefore, the ability of parental management techniques to predict antisocial behavior in general is questionable at best. Furthermore, while studies utilizing separate statistical models for males and females often find marked gender differences, the majority of these studies fail to statistically test whether these gender disparities are statistically significant (Fagan 2015) making it difficult to assess whether these observed gender differences are actually meaningful. On a separate note, if parenting factors are to explain male-female differences in offending, females must be exposed to protective parenting practices more frequently than are males, while males must be subjected to a greater amount of parenting practices that are linked to delinquency than females (Beaver and Nedelec 2015). Although many scholars have theorized that parents socialize their sons and daughters differently, a meta-analysis investigating this claim found that only 1 out of 19 areas of parenting styles was significantly different between boys and girls (Lytton and Romney 1991). Taken together, the empirical evidence suggests that parental socialization

factors can, at best, account for only a small portion of the observed variance in male-female aggression.

Much of the research just reviewed indicates that social factors do in fact influence sex differences in aggression to some degree. None of the social variables mentioned, however, can fully account for the relationship between sex and aggression, leading criminologists to investigate the association using multivariate models. Multivariate models are beneficial because they are able to examine the effects of multiple risk- and protective-factors simultaneously. Findings from multivariate studies including cultural, peer, and parental variables reveal that even though the effect of gender may be substantially reduced in such models, sex differences do in fact persist (Junger-Tas et al. 2004; Moffitt et al. 2001). For example, a multinational study conducted by Junger-Tas et al. (2004) controlled for a wide range of social variables that have demonstrated an association with antisocial behavior in prior research. Although they found that males were significantly more delinquent than females in each country they surveyed, their multivariate analysis found no significant sex differences for the majority of the social variables studied, including familial social controls, school ties, and peer influence. Empirical evidence such as this has led some researchers to investigate the possibility that nonsocial influences account for the sex differences in aggression.

Biological Influences on Offending

Although the variables responsible for the sex disparities in antisocial behavior remain under investigation, this body of research has confirmed two things. First, sex differences in behavior emerge shortly after birth, with one study revealing that gender differences in assertiveness can be observed even at the early ages of 13 to 24 months, with males being much more assertive than females (Tremblay 2006). Second, the gender differences in aggression that emerge early in life continue throughout virtually every stage of the life course (Moffitt et al. 2001). These two pieces

of information suggest that variables capable of explaining the sex differences in offending must also occur early in life and continue over time. Thus, while criminological research has historically focused on social variables to explain the fundamental differences in male and female antisocial behavior, an emerging body of research has begun to investigate the influence of biological and genetic factors. This growing body of research indicates that several biological factors play an important role in the gender gap in offending. These factors include neurological features, social cognitive skills, differential exposure to hormones, as well as genetic risk and susceptibility.

Neurological Influences

The early emergence of sex differences in behavior have led scholars to question whether neurological factors may be responsible for the male-female differences in antisocial behavior. One area of this research investigates developmental differences in the brain that occur between the sexes. Developmental differences begin to occur in utero and are responsible for differences in both the structure and function of male and female brains. These differences are proposed to play a significant role in the variance between male and female behavior (Wright et al. 2015). For example, empirical research has demonstrated that one outcome of these structural and functional disparities is that females tend to experience greater feelings of empathy than males (Tibbetts 2013). As mentioned previously, empathy is a strong protective factor, decreasing one's odds of participating in antisocial behavior and therefore explaining some of the variance in male-female offending rates. Furthermore, females generally score higher compared to males on other measures of self-conscious emotions such as shame and guilt (Tibbetts 2013). Women therefore possess a greater amount of inhibitory social emotions than males (Tibbetts 2013) and these emotional differences are likely behind some of the variance in the association between sex and aggression (Tibbetts 2013). It is likely that the differences men and women experience with regards to self-conscious emotions and social cognitive skills are linked to

structural and functional differences located within the brain.

On average, male brains are approximately 100 grams heavier than female brains are. While at one point in time, this led researchers to believe that male brains were superior to female brains, a closer investigation has resulted in this theory becoming mainly obsolete in the academic world. Specifically, although female brains have less mass than male brains, female brains have a greater efficiency in communication between brain cells which is likely due to the greater number of dendritic connections present (Wright et al. 2015). Moreover, females tend to have a higher level of neurotransmitters, including those which have been directly implicated in the brain's ability to regulate emotions and behavior (Wright et al. 2015). Research suggests that neurotransmitter interactions differ between males and females, and these differences are likely to contribute to the observed sex differences in self-conscious emotions and social cognitive skills (Wright et al. 2015). In addition to having more efficient communication between brain cells, the left and right hemispheres of the female brain appear to be better connected than in the male brain, allowing females to transfer information between hemispheres more quickly and efficiently than males. This superior connectivity may be a consequence of a larger corpus callosum in the female brain. The corpus callosum is one region responsible for the connectivity between brain hemispheres, and empirical research has demonstrated a link between the corpus callosum and the acquisition of self-awareness and intelligence (Halpern 2000).

Structural differences between the sexes are not only revealed when studying the brain as a whole but can also be seen when studying various regions within the brain. Studies assessing the neurological effects on aggression, violence, and impulse control have implicated several of these brain regions in the development of these behaviors (Raine 2008), therefore suggesting they may play a critical role in the gender disparities in antisocial behavior. In particular, research has revealed two brain regions that likely play an important role in explaining the sex disparities in

aggression: the limbic system and the prefrontal cortex.

The limbic system, considered a more primitive part of the brain, controls for basic emotions (i.e., anger, fear, pleasure) and human drives (i.e., sex, hunger) and includes structures such as the hippocampus, hypothalamus, cingulate gyrus, and the amygdala, among others. This area of the brain has been consistently linked to aggression, with an emphasis on the more serious forms of violence, including murder (Beaver 2009; Wright et al. 2015). Neuroimaging studies have consistently shown significant differences between the sexes in regard to the size of the neurological structures within the limbic system. For instance, females tend to have a larger cingulate gyrus than males, and this structure plays an important role in regulating emotions and behavior (Wright et al. 2015). Research is currently investigating whether having a larger cingulate gyrus may be responsible for the greater emotional responses reported by females. On the other hand, neuroimaging studies have revealed that the hippocampus, hypothalamus, and amygdala are larger in male brains versus female brains (Wright et al. 2015). Numerous studies have consistently demonstrated that these structures, especially the amygdala, are associated with the most serious forms of antisocial behavior such as murder and psychopathic personality traits (Raine 2008; Wright et al. 2015). Because these structures are larger and more active in males than females, the limbic system may be a key variable in understanding male-female differences in aggression.

Significant differences in size and performance between male and female brains have also been noted in the prefrontal cortex. The prefrontal cortex is perhaps the most studied area of the brain in regard to its association with antisocial behavior, with results consistently demonstrating a significant and fairly strong relationship between disruption in – or damage to – the prefrontal cortex and aggression (Beaver 2009; Raine and Yang 2006; Wright et al. 2015). The prefrontal cortex is responsible for higher-order cognitive processes, collectively known as executive functions. The most important higher-order cognitive processes

in reference to antisocial behavior include interpreting incoming stimuli, processing emotions, and deciding on an appropriate response to the incoming stimuli. Neuropsychological studies have repeatedly found that damage to the prefrontal cortex results in executive functioning deficits, and, in turn, an increase in antisocial behavior (Raine 2008).

Results from brain imaging studies have confirmed that women typically have larger and more active prefrontal cortices than men (Wright et al. 2015). This is an important fact when considering the role of the prefrontal cortex in regards to male-female differences in offending and aggression. The executive functions that occur within the prefrontal cortex serve as an “emergency brake” on the strong emotions generated by the limbic system (Beaver 2009; Raine 2008; Wright et al. 2015). Because males have larger and more active limbic structures than females combined with a comparatively smaller, less active prefrontal cortex than females, they are expected to participate in antisocial behavior at a greater rate than females. Empirical studies confirm that this is a strong possibility by consistently demonstrating that males not only commit more crime than females but also that males report higher levels of impulsivity and lower levels of self-control than females.

In a more general sense, Raine and Yang (2006) proposed a neural moral theory of antisocial behavior in which abnormalities occurring to the neural circuit activated during the normal moral decision-making process can lead to an increase in antisocial behavior. That is, if one of the brain regions critical to moral feelings and decision-making does not function properly or is structurally altered or damaged, that individual is at an increased risk for a breakdown in moral feeling which can ultimately lead to a rise in criminal behavior. Male’s neural morality may naturally be lower than female’s neural morality due to the fact that regions of the brain imperative for morality and decision-making are comparatively smaller and less active in male brains than they are in female brains. Although more research is needed, the available empirical evidence suggests that neurological differences may play a

vital role in the explanation of male-female differences in aggression.

Hormones

Androgens, the group of hormones that primarily influence the growth and development of an individual (i.e., testosterone, estrogen), may play a critical role in the gender disparities in aggression. All human brains begin to develop according to a female trajectory. Around the 8th week of gestation, a gene located on the Y chromosome – a chromosome specific to males – signals the brain to create testosterone which initializes a separate growth trajectory for males. Researchers believe that the formation of sex differences in the structure of the brain primarily takes place at approximately 34–41 weeks of pregnancy (Halpern 2000). Studies have discovered that during this time period, androgens are typically ten times greater in male fetal brains than in female fetal brains (Halpern 2000). Therefore, hormones – specifically testosterone – are thought to be primarily responsible for the significant structural and functional differences in male and female brains (Baron-Cohen 2004).

Empirical research investigating the effects of hormones on sex differences in antisocial behavior are limited, however, most likely due to the difficulty in measuring hormone levels. Prenatal exposure to testosterone is considered one of the key causal factors behind the variation in male and female brain structure (Baron-Cohen et al. 2004) but gaining access to measures of testosterone levels in utero is quite difficult. According to a review by Beaver and Nedelec (2015), the only means of gaining direct measures of prenatal testosterone are rather invasive and include testing blood from the umbilical cord after birth, testing maternal serum derived from venipuncture, or by testing amniotic fluid which is acquired through amniocentesis. These obstacles in gaining access to prenatal testosterone levels have limited the amount of empirical evidence garnered from studies utilizing direct measures. Moreover, studies that do include such measures typically do not include measures of antisocial behavior (Beaver and Nedelec 2015). Findings from this small body of research reveal that higher testosterone levels

occurring in utero are associated with a higher degree of masculine behavior (Baron-Cohen et al. 2004).

A small but growing body of research has utilized indirect measures of prenatal testosterone levels to examine the association between testosterone and behavior. The 2D:4D ratio is perhaps the most popular of the indirect methods and is calculated by dividing the length of the index finger by the length of the ring finger. This ratio is sexually dimorphic, becomes relatively stable around the 14th week of gestation, and changes little, if at all, over the life course. The 2D:4D ratio thereby serves as a rudimentary measure of exposure to testosterone in utero, where a lower ratio indicates higher levels of prenatal testosterone (Lutchmaya et al. 2004). Males typically have a lower 2D:4D ratio than their female counterparts (Lutchmaya et al. 2004), which is not surprising considering the evidence that has demonstrated greater testosterone levels in male fetus brains versus female fetus brains (Halpern 2000). Less obvious, however, is the relationship between the 2D:4D ratio and antisocial behavior. A number of studies investigating this association have found that a lower 2D:4D ratio is positively correlated with an increase in aggressive behaviors (McIntyre et al. 2007). Moreover, these studies typically show that the 2D:4D ratio is associated with an increase in aggression for males but not females (McIntyre et al. 2007), although at least one study found that this ratio did predict an increase in reactive aggression for females. Taken together, these studies seem to indicate that greater exposure to testosterone in utero can lead to an increased risk in antisocial and aggressive behavior.

Although findings from these initial studies are positive, the results from a recent meta-analysis are varied. Hönekopp and Watson (2011) found a moderate difference in the 2D:4D ratio between the sexes with a lower ratio for males. Their study also found that research investigating the correlation between the 2D:4D ratio and various outcomes suffered from measurement bias, with results varying based upon whether the studies used self-reported ratios or ratios measured by experts as well as the parts of the finger included

in the measurement (Hönekopp and Watson 2011) making it difficult to assess the validity of previous studies. These mixed results indicate more work is needed in this area before any conclusions can be drawn.

Another indirect measure of prenatal testosterone levels examines individuals who suffer from disorders that disturb the normal exposure of testosterone in utero. Females suffering from congenital adrenal hyperplasia (CAH), a disorder that causes an increase in testosterone levels in both prenatal and postnatal life stages, are often analyzed in clinical studies investigating the association between increased testosterone and an array of behaviors (Beaver and Nedelec 2015). These females are exposed to much higher levels of testosterone in utero than are females who are not afflicted by this disorder, and scholars therefore theorize females with CAH will differ significantly in behavior and cognition. In regards to aggression, overall results suggest a positive correlation between CAH and an increase in antisocial behaviors (Pasterski et al. 2007). The most recent study conducted by Pasterski et al. (2007) found that although females stricken with CAH were significantly more aggressive than their sisters not suffering from CAH, males – both with and without CAH – continue to display more aggression than both female groups.

Taken together, results from these three lines of research indicate a positive relationship between greater levels of testosterone in utero and an increase in antisocial personality traits and aggressive behavior. In addition, adolescent testosterone levels have also been linked to antisocial behavior. When male and female offending is at its peak, they are simultaneously experiencing a surge in the production of androgens (Beaver 2009). Therefore, the majority of female offending occurs during the age span that testosterone production is at its highest rate since before birth.

Aside from producing aggressive behavior, androgens also have the ability to protect an individual against engaging in antisocial behaviors. For example, at least one study has found that estradiol, or estrogen, appears to aid an individual in their ability to cope with stress. Estradiol/estrogen is primarily produced in the ovaries, and

therefore women tend to have higher levels of estrogen when compared to males. This finding is important since stress is a known risk factor for criminal involvement and aggression. Collectively, initial evidence from empirical studies seems to suggest that while androgens act as a risk factor for delinquency in males, they also serve as a protective factor for females. There is a need for replication of these findings, and therefore, the ability of the relationship between androgens and aggression to explain the difference between male and female aggression remains an open empirical question and should be addressed in future research.

Genetics

Differential genetic makeup between males and females may also play a role in explaining the gender gap in offending and aggression. For example, a study conducted by Vaske et al. (2011) proposed that the genetic risk threshold is higher for females than it is for males. That is, males require less genetic risk factors to influence their criminal behavior than do their female counterparts. Findings from this study yielded mixed support for the theory, however. While the study found that the genetic risk threshold was indeed higher for males than females, females that did commit an offense had significantly less genetic risks than the male offenders (Vaske et al. 2011). Although these findings provide some evidence for the role of genes in the differential development of antisocial behavior between the sexes, it is clear that more research is needed before any solid conclusions can be drawn.

One possible explanation for the gender differences in antisocial behavior may be the location of the genes associated with aggression. While males possess both an X and Y chromosome, females possess two X chromosomes. Therefore, if a risk allele is located on the X chromosome females have two copies of this gene, while males only have one. This makes risk alleles located on the X chromosome particularly risky for males because a female's second X chromosome can help counteract the genetic risk by providing a second, potentially unaffected, version of this gene (Beaver 2009). This line of thinking has

been substantiated in the case of the low activity allele for monoamine oxidase A (MAO-A), which has been consistently found in empirical studies to have criminogenic effects on males (Beaver 2009; Caspi et al. 2002).

In a landmark study, Caspi et al. (2002) demonstrated that a polymorphism of the MAO-A gene, specifically the low activity allele, interacted with childhood abuse to predict an increase in feelings of violence, conduct disorder, antisocial personality disorder, and violent offenses for males. Although this study did not include females, empirical research conducted since this study has begun to examine the effect genetic polymorphisms of MAO-A have on females as well. Results from these studies reveal that the low activity allele of MAO-A does not predict female antisocial behavior as it does with males (Prom-Wormley et al. 2009). These results do not indicate, however, that females are not affected by MAO-A at all. In fact, multiple studies have found that an interaction between the long variant of the MAO-A polymorphism and childhood abuse significantly predicted an increase in delinquency for females but not males (Prom-Wormley et al. 2009). While findings from this body of research demonstrate a robust correlation between MAO-A and aggression, the ability of MAO-A polymorphisms to partially explain the gender gap in offending requires further investigation.

In addition to the MAO-A gene, genetic polymorphisms from the dopaminergic and serotonergic system have also been implicated in the etiology of various antisocial and violent behaviors (Beaver 2009). These studies do not typically include females, however, so whether genetic polymorphisms from these systems can explain the differences in male-female aggression remains undetermined and should be investigated in future research. Although research assessing the relationship between genes and gender disparities in aggression are rather limited, evidence from the few studies available seem to point to a positive relationship between genetic risk and aggression. Genetic research therefore has great potential for explaining sex differences in aggression and offending.

Conclusion

Across time and space, males have been found to be more criminally prone than females, so much, so that criminological inquiry is virtually required to statistically control for the effects of gender. Empirical research has consistently found that sex differences in aggression begin shortly after birth and remain relatively stable over various stages of the life course. Males are far more likely than females to become life-course persistent offenders (Moffitt et al. 2001), and gender disparities are greatest for more serious and violent crimes such as robbery, rape, and murder (U.S. Department of Justice 2009). Although the relationship between gender and crime is robust, the causes of male-female differences in criminal behavior remain largely undetermined. Researchers have investigated both social and biological variables in the quest to discover what factors produce sex differences in aggression and crime.

While studies have consistently found a relationship between sociological factors such as cultural values, community influences, peer associations, and familial factors and the gender disparities in aggression, the possibility that these variables are the sole factors behind the gender gap is unlikely. For example, studies consistently find that gender remains a significant predictor of a range of antisocial behaviors, even when utilizing multivariate models that account for multiple sociological risk factors. Furthermore, the early emergence of male-female differences in aggression coupled with the relative stability of the relationship over the life course sheds doubt upon the claim that environmental factors can explicate the relationship between sex and antisocial behavior. In order for socialization factors to be able to explain male-female differences in aggression, they would need to occur shortly after birth and have a major and salient effect on the individual over the life course. Empirical studies have yet to discover an environmental factor that fulfills these criteria and therefore cannot currently support this claim (Beaver and Nedelec 2015).

Given that sociological variables leave a large portion of the variance between male and female offending unexplained, scholars have turned to

biologic and genetic factors to potentially explain such sex differences. Differential neurologic development results in structural brain differences between males and females in utero. These enduring structural differences are responsible for functional disparities in male and female brains that transpire over the life course. These structural and functional discrepancies in male and female brains have been linked to sex differences in an array of phenotypes, including antisocial behavior (Raine 2008; Wright et al. 2015). Variation in androgen production between the sexes may also be partially responsible for sex differences in aggression throughout the life course. Androgens are partially responsible for the differences in neurological development that occur in utero, and increased androgen production in adolescence has been correlated with the increase in antisocial behavior seen during this life stage (Beaver 2009). Empirical research has also begun to discover that differences in genetic makeup between the sexes may also partially explain male-female differences in aggression (Beaver 2009). Biological and genetic differences therefore have the capability of explaining male-female differences in aggression that are evident shortly after birth and continue over time.

Although neurological, hormonal, and genetic factors appear to explain a greater portion of the variance in male-female antisocial behavior than purely environmental factors, a percentage of the variation remains unexplained. Taking into consideration the evidence reviewed here, it seems plausible that the effects of sociological factors enhance the naturally occurring biologic and genetic differences in males and females to create sexual differences in antisocial behavior. That is, biological or genetic risk factors may exist within an individual but remain dormant or underactive until exposed to certain environmental factors (i.e., child abuse). Although research in this area is just beginning to emerge, the limited amount of empirical evidence available demonstrates that genetic factors interact with environmental variables to produce antisocial behavior (Caspi et al. 2002; Raine 2008). Furthermore, research has demonstrated that males possess a greater number of genetic risk factors than females (Vaske et al.

2011) and also report higher rates of environmental criminogenic risk factors (Moffitt et al. 2001).

Future research would benefit from integrating the vast knowledge concerning biological differences between males and females into sociological theories of crime causation. Biosocial factors appear to have the greatest potential for explaining the variance in male-female aggression. Understanding how biological and genetic factors may interact with environmental factors to create disparities in offending behavior between the sexes can lead to public policies of crime control that are more fully informed. For example, programs aimed at changing criminogenic environments and lowering biological risk factors may effectively lower criminal propensity for both males and females. Identifying the causes behind sex differences in crime and aggression can also lead to the creation of effective treatment programs. Much of the available evidence suggests that the influence of criminogenic risk factors vary between males and females, therefore treatment programs would benefit from identifying and focusing on the factors that are most salient for each sex.

Definition

Some elements of anger proneness demonstrate sex differences.

Introduction

Psychological sex differences have been documented for numerous traits in many cultures. The current debate in the field addresses the magnitude, uniformity, and basis of these differences. Traditionally, psychological sex differences have been attributed to social roles. Evolutionary psychology, however, views sex differences as rooted in genetic variations that have developed through natural selection. According to evolutionary theory, males and females exhibit different behaviors since each had to deal with different challenges in the prehistoric past. For example, physical aggression is more prevalent in males than in females. Archer (2009) suggested that this is a result of an evolutionary cost-benefit analysis. For males, aggression can confer benefits of increased reproduction, which may outweigh the costs of danger and injury. For females, however, aggression bears more severe risks and delivers smaller gains. Unlike physical aggression, Archer (2009) claimed that indirect aggression and anger would not offer a clear benefit for one of the sexes, and therefore, sex differences would not be anticipated (Archer 2009). Archer theorized that while both sexes have reasons for becoming angry, males have stronger reasons for expressing that anger aggressively. As a result, this has led to a sexual selection for aggression, but not for anger (Archer 2009).

Sex Differences in Anger

Meta-analyses on sex differences in anger have revealed mixed findings. Archer (2004) conducted a meta-analysis of 46 samples that assessed sex differences in the anger subscales of aggression scales. Consistent with his theory, he found a sex difference for physical aggression, but not for anger ($d = -0.003$). A more recent

meta-analysis conducted by Chaplin and Aldao (2013) comprised 77 studies on anger expression in children. This analysis used a wider measurement of anger, including not only scales measuring aggression but also any scale the original authors identified as an anger scale. Contrary to Archer's suppositions (2004), Chaplin and Aldao (2013) found that boys expressed more anger than did girls ($g = 0.10$).

Large-scale studies of anger have also provided mixed results. Kajonius and Johnson (2018) studied the responses of 320,128 Americans to the IPIP-NEO-120 (the open access version of the five-factor model of personality). The anger subscale of neuroticism revealed no statistically significant sex difference for anger ($d = -0.16$, with females scoring slightly higher in anger than did males).

On the other hand, Asgeirsdottir and Sigfusdottir (2015) found different outcomes in their assessment of 8038 Nordic adolescents' anger. They used five anger items based on the Symptom Checklist-90 (SCL-90), a measure of psychopathological symptoms. In their study, girls reported higher levels of anger in four of the five countries studied.

Components of Anger

The reason for these discrepancies may lie in the operationalization of the anger construct. Spielberger was one of the first to assess and define anger (see the historic review of Spielberger and Reheiser 2009). Spielberger distinguished between state and trait anger. State anger was defined as "a psychobiological state or condition, consisting of angry feelings that may vary in intensity...with associated activation of the autonomic nervous system" (Spielberger and Reheiser 2009, p. 281). Trait anger is determined by the frequency that state anger is experienced (Spielberger and Reheiser 2009, p. 281).

In addition to differentiating between state and trait anger, Spielberger theoretically recognized the overlap of three concepts, anger, hostility, and aggression, which he named collectively as AHA! A later psychometric study confirmed that anger comprises a three-factor construct (Martin et al. 2000). The

researchers explored eight self-report anger scales, with 24 subscales, using a sample of 457 American undergraduates, confirming that indeed anger scales measure three factors: anger, hostility, and aggression. Each of these factors has different associations with the Big Five personality traits. Anger is the affective component, linked to neuroticism. Aggression is the behavioral component, related to low agreeableness. Hostility (or cynicism) is the cognitive component, linked to both neuroticism and low agreeableness (Martin et al. 2000).

Sex Differences in the Elements of Anger

This three-factor structure of trait anger did not differ between men and women. When considered separately, the male and female data yielded almost identical three-factor solutions (Martin et al. 2000). These similarities notwithstanding, there were, nonetheless, significant sex differences in the factor scores. Women scored higher than did men on the affective component of anger ($d = 0.40$). This pattern was reversed for behavioral aggression, with men scoring higher than did women ($d = -0.98$). Hostile or cynical cognitions showed no significant sex difference ($d = -0.02$; Martin et al. 2000).

Conclusion

Meta-analyses and large-scale studies have produced mixed results regarding the sex differences in anger. These discrepancies may result from the lack of uniformity in their measurement. It appears that while women score higher on the affective element of anger, men score higher on its behavioral element.

differences in adult attachment and that these differences may be first evident during middle childhood. Despite the controversy, I would propose that the suggestion that there may be sex differences in attachment should not be surprising. It is well accepted that women and men tend to be socialized differently from birth (Bem 1993) and, as a result, men are typically less emotional and less nurturing than women. Furthermore, there is support that women and men may perceive social interactions differently and consequently behave differently in their relationships. Despite the proposal that attachment representations and gender roles have a joint influence on behavior of adults, sex differences in attachment do not seem to be evident during infancy and preschool years, and there are inconsistent reports of sex differences during the school age years (see Del Giudice 2008 for summary of this research). Furthermore, sex differences in adulthood are not consistently reported but tend to be evident with self-report questionnaire measures, in particular measures of Bartholomew's four-category model. It does seem clear that the ability to detect (or not) sex differences in attachment may be associated with the type of assessment, the power to test for differences, and characteristics of the sample.

Sex Differences in Attachment

Elaine Scharfe

Trent University, Peterborough, ON, Canada

Definition

There is some evidence that men and women have moderately different distributions of insecure adult attachment styles. Generally, men may tend to report higher avoidance and women may tend to report higher ambivalence, but these findings are somewhat inconsistent and controversial.

Introduction

Although controversial, there is some empirical evidence that there may be small to moderate sex

Sex Differences in Attachment

Over the past 40 years, attachment researchers have consistently reported that most individuals in low risk or nonclinical samples, regardless of the age of the participants or method of assessment, are secure. Although there are no sex differences in the proportion of secure and insecure individuals, some researchers have reported sex differences in proportions of the type of insecure attachment. Furthermore, some researchers have proposed that these differences may be adaptive and predictable. For example, Del Giudice (2009) proposed an evolutionary model that, among other things, proposed that women develop insecure-ambivalent attachment in conditions of moderate stress in childhood and avoidant attachment under conditions of high stress whereas men

develop insecure-avoidant attachment when they experience stress in childhood. Interestingly, very little attention has been paid to the effects of the gender of the caregiver on the developing attachment relationship. Mothers typically invest more in the parent-child relationship and are usually a child's primary caregiver. However, it is unknown if this primary attachment is more influential, in particular, in situations where, for example, the attachment relationship with the mother is different than the attachment relationship with the father.

Del Giudice and colleagues have proposed that sex differences in attachment may develop in middle childhood (see Del Giudice and Belsky 2010) although the proposal is somewhat controversial (see Thompson 2010; van IJzendoorn and Bakermans-Kranenburg 2010). Early work measuring infant attachment using the Strange Situation tends not to mention sex differences in attachment; however, early behavioral work consistently reports that, in preschool aged children, insecure males tend to be more aggressive whereas insecure females tend to be more dependent and compliant. These findings are consistent with the observed sex difference that when stressed males tend to engage in "fight or flight" behaviors, females tend to engage in "tend and befriend" behaviors.

There are a few studies reporting sex differences in middle and late childhood and nearly all report a sex difference in the categorization of the insecure children: more ambivalence in females and more avoidance in males. These gender differences have been reported in studies using several different methods of assessment including versions of the Doll Story Completion Task, The Manchester Child Attachment Story Task, and the Coping Strategies Questionnaire. Although some researchers continue to insist that these sex differences are not meaningful, Del Giudice and Belsky (2010) proposed that the life history perspective and neurobiological developmental changes may help to understand why middle childhood may be an important transition with respect to the development of sex differences in attachment.

Del Giudice (2009) proposed an integrated evolutionary model of the development of attachment,

which among other things, may explain how and why middle childhood acts as a transitional stage in both the development of attachment and reproductive strategies. He proposed that this phase of reorganization of attachment may be due to "intrasexual competition in the peer group" and physiological and hormonal changes associated with adrenarche – both contributing to the development of sex differences to improve the adaptation of the insecure child. Although further work is needed to test his model, it builds upon Bowlby's original theory, which was firmly rooted in evolutionary thinking at the time, and provides insights from modern evolutionary theory to explain why attachment researchers may observe sex differences in adult attachment.

Sex Difference in Adult Attachment

Early work using the AAI does not suggest sex differences in attachment, however, as with many studies using interview assessments; the samples were typically small and may not have had sufficient statistical power to test for differences. Bakermans-Kranenburg and van IJzendoorn (2009) summarized the data from over 10,000 AAI interviews addressing issues of base-line proportions in clinical and nonclinical samples, gender distributions, as well as differences in distributions for adolescents and individuals from low SES samples, ethnic minorities, and non-Western countries. Using the AAI four-category classification of a sample of nonclinical mothers ($n=700$) as their baseline, their findings indicated that nonclinical fathers were more likely to be classified as dismissing. Although there were no significant differences with the preoccupied category, despite the large number of interviews in both groups, the authors only had sufficient power to test for large differences between the proportions of individuals categorized as preoccupied. Using the AAI dimensions, which increases the power to test for differences, Simpson et al. (2002) reported that men scored significantly closer to the dismissing end of the activation continuum whereas women scored significantly closer to the preoccupied end.

Although Hazan and Shaver (1987) did not report sex differences in their original article using the three-category measure, researchers consistently report sex differences with Bartholomew's four-category model (see Bartholomew and Horowitz 1991). Bartholomew and colleagues have reported that females and males do not tend to differ on their secure or fearful ratings; however, females tend to score higher than males on the preoccupied scale and lower than males on the dismissing scale. These sex differences are evident when using both Bartholomew's family and peer interviews as well as both the categorical and continuous self-report surveys. Partner- and friend-reports reveal similar sex differences (see also Scharfe and Bartholomew 1994). Interestingly, Schmitt et al. (2003) analyzed the RQ data across 62 countries and reported small to moderate sex differences in dismissing attachment across most cultures – in particular, cultures characterized by low stress and low fertility environments – and concluded that greater levels of dismissingness in males is “near universal.”

The introduction of the ECR and the ECR-R did not include a discussion of sex differences so it is not known whether or not sex differences were tested in the original data (see Brennan et al. 1998; Fraley et al. 2000). Furthermore, there are few researchers who test (or report) sex differences in published work using the ECR or the ECR-R, although it is not clear whether or not there are no sex differences on the two dimensions or that the researchers simply did not test for sex differences; however, there are a few exceptions. For example, in a recent meta-analysis, Del Giudice (2011) reported a significant but small sex difference in that men scored higher on the avoidance dimension and lower on the anxiety dimension. Interestingly, he found that these sex differences were stronger in community samples. Del Giudice suggested that there are consistent sex differences in attachment; however, there are variables such as the distribution and type of the sample, geographic region, the non-normal distribution of the data, unreliability of the measures, and effect of age that may confound the results.

As pointed out by some scholars (see Del Giudice and Belsky 2010), the fact that researchers find sex differences with some measures, and in some samples, and not with other measures or samples is likely meaningful and should not be ignored. As suggested above, it is well accepted that women and men are socialized differently and perceive and behave differently in their relationships and perhaps it would be productive to examine the joint influence of attachment representations and sex role on behavior in relationships. For example, it is well accepted that attachment avoidance is related to a greater number of less-committed relationships for both men and women whereas attachment anxiety is associated with dependency and possessiveness for both men and women. Perhaps a fruitful direction for research – to help to understand the importance of sex differences – would be the examination of those findings in which gender boundaries are crossed. In particular, it may be helpful to examine the research describing relationship characteristics of anxious-ambivalent men or avoidant women. The few studies that have highlighted these unexpected sex differences highlight the importance of these differences in understanding the effects of attachment representations on adult relationships.

There is some evidence that preoccupied or ambivalent attachment for men and dismissing or avoidant women may have a more negative effect on their relationships and well-being. For example, Simpson et al. (1999) reported that highly ambivalent men's relationships (as compared to relationships of other men and all women) were more likely to have ended over a 4-month period suggesting that highly ambivalent men may have less successful relationships. Furthermore, Kanninen et al. (2003) reported that preoccupied men had a heightened affected response to traumatic events and were proposed to be vulnerable to the emotions and distress associated with past traumatic events suggesting that highly ambivalent men may have more difficulty coping with difficult life events. Similarly, Bodner et al. (2014) reported some evidence that, in early adulthood, preoccupied men may experience a significant decline in their reports of the meaning

of life. Consistent with the suggestion that women may develop avoidant attachment under extreme stress, there is also some support that avoidant women may have more difficulty in their interpersonal relationships. For example, Mikulincer and Florian (1999) reported some evidence that avoidant women showed weaker attachment to their fetus and more negative prenatal mental health. Rholes et al. (1999) reported that more avoidant women displayed more anger while waiting for an “anxiety provoking” situation with their partners, and Simpson et al. (2002) reported that more avoidant women provided less support to their partners regardless of his attachment. Although these studies provide some evidence that anxious-ambivalent men and avoidant women have more difficulty in relationships and coping with life events, very few studies systematically examine the differential effects of attachment across gender, and a more comprehensive examination of this issue is needed.

Conclusions

In summary, although the findings are inconsistent and controversial, there is some support that, at least in adulthood, men may tend to report higher avoidance and women may tend to report higher ambivalence. There are, however, incidences where women report higher avoidance and men report higher ambivalence and these findings might be more interesting and productive to understand the importance of sex differences in attachment. As researchers continue to explore this controversial issue, it will be interesting to pay particular attention to the effect when individuals go against the “norm” – what is the effect when the insecure female or male is “different” than what would be expected. I would suggest that both the typical and the atypical sex differences will be informative.

Sex Differences in Attractiveness of Humor

Kay Brauer and René T. Proyer
Department of Psychology, Martin Luther
University Halle-Wittenberg, Halle (Saale),
Germany

Synonyms

Attractiveness; Courtship; Humor; Mating preferences

Definition and Introduction

A good (sense of) humor is among the most frequently desired qualities in potential short- and long-term partners, and numerous studies found humor to be an important characteristic that people seek in close others. This entry gives a short overview on why humor is considered to be

among the most attractive traits and also on the role of sex differences, from a theoretical and an empirical view.

Theoretical Suggestions on Why Humor Is Perceived as an Attractive Trait

While humor can be described across several quantitative and qualitative characteristics, we will use the term in a broad sense in this entry and primarily differentiate between humor *production* and *appreciation* (in the sense of responding to a humorous stimulus); for an overview, see Martin and Ford (2018) and Ruch (2007, 2008). Numerous studies have shown that humor plays a role in social life across different social domains (e.g., work vs. romantic life) because people use humor for bonding, cooperation, and maintaining relationships (e.g., by decreasing tension in conflicts). Hence, humor contributes to social interplay and appears to be one of the most desired traits in close partners.

The question *why* humor is valued as an attractive trait in partners has been discussed across two theories. Firstly, *sexual selection theory* (SST) assumes that individual differences in humor appreciation, comprehension, and production signal underlying qualities that are important for sexual selection and mating choices, as they signal the genetic quality that contributes to survival and reproduction. Among others, Miller (2000) argued that producing and understanding humorous content is based on cognitive efforts, which reflect abilities such as intelligence and creativity. This notion found substantial support across studies, as measures of humor production and preferences were positively related to a wide range of psychometric tests of cognitive functions such as verbal, figural, and general intelligence, as well as indicators of creativity (for an overview, see Greengross 2014; Kaufman et al. 2008). In line with the notion of humor being relevant for sexual selection and indicating underlying qualities, one might expect that humor-related traits would be passed on genetically. Initial evidence from twin studies lends support to this view, as shared

genetic variance explains humor appreciation to an extent that cannot be traced to environmental influences (e.g., Weber et al. 2014; see also Kaufman et al. 2008). Finally, positive relationships among intelligence, creativity, and humor abilities (i.e., producing humorous content) and their unique relationships with mating success support SST (e.g., Greengross and Miller 2011). Overall, the literature supports the notion that humor is related to important qualities that have reproductive value (i.e., intelligence, creativity; also referred to as *genetic quality*).

In SST, sex differences are emphasized. Men are expected to engage in producing humor to signal their humorous qualities, whereas females evaluate men's humor. Women participate in courtship by means of their responses to men's humor: namely, they signal romantic interest by appreciating men's humor attempts (e.g., by openly displaying appreciation through laughter). Moreover, it has been suggested that men use humor for intrasexual competition, when it is used to gain status in comparison to other men in order to attract the attention of a potential female partner.

Alternatively, Li and colleagues (2009) proposed the *interest indicator model* (IIM), which assumes that humor is a means of communicating mating interest *after* attraction to a potential partner is established. It has been observed in animals that a playful and humorous interaction (i.e., *play face*) creates an interpersonal environment in which actions and communication are of low seriousness. Based on this notion, Li et al. argue that using humor can convey romantic interest within such a safe environment and can save face in case of rejection by the partner. Therefore, the IIM would predict that humor does not signal underlying qualities of cognitive ability but that indicators of intelligence (e.g., engaging in a meaningful conversation) would predict mating success independently from humor. Moreover, the IIM assumes no sex differences in the usage of humor and as an indicator of interest it is not limited to the romantic domain (e.g., it also occurs with colleagues at work). While initial evidence supports the notions of the IIM, further research is warranted.

Major Findings on Sex Differences

The role of humor in courtship has been studied empirically using numerous methods since the 1950s. For example, analyses comprised people's rankings of desired characteristics and behavioral acts (e.g., "display a good sense of humor"; "appreciating his/her humor") for different types of relationships (e.g., short-term vs. long-term partners), interactions in the laboratory (e.g., speed-dating), reactions to scenarios and vignettes displaying fictitious partners, or the analysis of adverts and profiles on dating platforms in online and print media. An overview of key studies on the topic, which aims to give a short overview of important studies in the field, sample sizes, the employed methods, and key findings, can be found under osf.io/jxkg8/.

Studies examining mate preferences by asking people what attributes they desire in romantic partners have shown that "(good sense of) humor" is ranked among the most important qualities independently from sex. This finding has also been replicated numerous times since the 1950s and across methods: for example, when using economic games in which participants can distribute money to attributes in a potential partner according to what they view as important. Moreover, this finding is robust across different types of relationship-partners (e.g., dating-, short-term, and long-term partners) and sexual preferences (homo- and heterosexuality). People also report that displaying a good sense of humor is perceived as a successful tactic to attract a potential partner.

While no robust sex differences exist for desirability rankings when humor is treated as a broad trait, the distinction between *appreciating* and *producing* humor reveals differences in what men and women prefer. In line with expectations derived from SST, females strongly prefer men who produce humor, with robust effect sizes across relationship types varying from loose (e.g., one-night stands) to strong bonding (e.g., marriage partner). Furthermore, there is evidence that men prefer females who appreciate their humor attempts, but findings are mixed for this association because the magnitudes of effects vary across studies. Interestingly, women also prefer

men who appreciate their humor attempts but only when men are also high in humor production. Thus, it has been suggested that humor appreciation by men is seen as a “luxury” addition, whereas humor production is a necessity for females’ attraction toward men. When extending research toward individual differences in dealing with ridicule and laughter, initial evidence shows that females who enjoy laughing at others are with male partners who engage in making others laugh, whereas the association is negligible for females’ dispositions to engage in making others laugh and men’s joy of laughing at others.

When testing SST assumptions in laboratory experiments, findings were in the expected direction but tended to yield small effect sizes. Generally, men were more inclined to produce greater quantities of humor than women, and women signaled greater appreciation in order to display romantic interest compared with their male counterparts. Overall, interaction studies support the sex effects of humor production, but findings for sex differences in humor appreciation and its relation to signaling dating interest are mixed, as some studies showed no association with romantic interest outcomes and/or differences in females’ and males’ usage. Moreover, studies using naturalistic interaction settings show that *shared* laughter may be an even better predictor of dating interest than one-sided appreciation, as it might suggest that both partners prefer and enjoy similar humor (i.e., quality and quantity).

Another line of research has studied the occurrence of desire toward producers and appreciators by analyzing dating ads. Findings from this line of research also support the notion that men are inclined to offer humor whereas women are more frequently described as seeking humor in men, although it has to be noted that findings for appreciation were less robust.

Conclusion

The literature in this field has generated two main findings. Firstly, humor is viewed as an attractive trait in others and is strongly desired,

independently of gender. This finding is stable and has been replicated well over the last 60 years. Secondly, distinguishing between humor appreciation and humor production is related to sex differences in perceptions of attractiveness. The majority of findings support the notion of SST, as females are attracted to males who produce humor whereas men prefer women who engage in appreciating their humorous attempts. However, it must be noted that findings on humor appreciation and effects of sex differences are less robust than those on humor production. Overall, SST gives a theoretical framework for the study of sex differences in attractiveness of humor.

Further research is needed to understand the role of humor in courtship. For example, one might assume that more fine-grained analyses of sex differences in the quality and quantity of humor attempts (cf. Ruch 2007, 2008; Ruch et al. 2018; see also Martin and Ford 2018) are differentially related to perceptions of attractiveness. Moreover, preferences of humor producers and appreciators may have interactive effects on mating outcomes (e.g., romantic interest).

The differences between boy and girls in cognitive development

Introduction

A diversity of studies in psychology and neuropsychology has approached the question of gender differences in cognitive abilities (e.g., Bjorklund and Causey 2017). Three major gender differences in cognitive abilities have been reported: (1) higher verbal abilities in women, (2) higher spatial abilities in men, and (3) higher arithmetical abilities in men. However, these three differences may be collapsed in only two as differences in calculation abilities may be the result of men's superior spatial abilities (Geary 1996).

Women usually score higher in a variety of verbal tests (e.g., Burton et al. 2005). They also present a faster language development (Berglund et al. 2005) and have a larger vocabulary, more accurate speech production, and greater fluency (Mildner 2008).

Gender Differences in Language Abilities

Despite the aforementioned reports and numerous publications in the same direction, gender differences in language abilities remain a controversial topic, as there are also judicious studies questioning the presumed higher verbal abilities in women. A meta-analysis of 165 language studies involving both children and adults and including a broad range of language tests (vocabulary, analogies, anagrams, reading comprehension, speaking or other verbal communication, essay writing, the Scholastic Aptitude Test (SAT) - Verbal, and general verbal ability tests) was conducted. Results were mixed: 44 (27%) of the studies reported that females outperformed males, 109 (66%) found no significant gender differences, and 12 (7%) found males outperforming females. The authors concluded that “the magnitude of the sex difference in verbal ability is currently so small that it can effectively be considered to be zero” (Hyde and Linn 1988, p. 64). An extensive review of gender differences in language among children concluded that “A small but consistent female advantage is found in early language development, but this gender difference

seems to disappear during childhood” (Wallentin 2009, p. 181). Reynolds et al. (2015) found in a sample of children and adolescents ranging from ages 7–19 years that girls scored higher on spelling and written expression.

In adults, sex differences in verbal abilities and in language-related brain structure are not readily identified. If they exist, they are not easily picked up with the current research methods used today (Wallentin 2009). Gender differences in language have also been reported during aging. It has been also observed that spontaneous language in general decreased with age; however, a significant interaction-effect between age and gender was observed. A steady and pronounced spontaneous language decrease across age-groups was observed in males. However, only mild differences across age-groups were found in females. Interestingly, the ratio among different phrase elements (nouns, verbs, adjectives, and grammatical connectors) was found to be very uniform across age, educational level, and gender groups (Ardila and Rosselli 1996).

There are also publications reporting boys outperforming girls in language skills. For example, (Ardila et al. 2011) analyzed gender differences in cognitive test performance among a large sample of Latin-American children from continuous age groups (5–16 years). Boys outperformed girls in oral language (language expression and language comprehension). However, gender accounted for only a very small percentage of the variance (1%–3%).

Why Gender Differences in Cognitive Development?

Some authors have emphasized that gender differences may arise from the dispersion in cognitive abilities between men and women rather than just the mean gender differences, for example, based on analyses of mental test scores from different studies. Although average sex differences have generally been small and stable over time, the test scores of males have consistently shown greater variance. Moreover, except for tests of reading comprehension, perceptual speed, and

associative memory, males typically outnumber females substantially among high-scoring individuals (Hedges and Nowell 1995).

The origin of gender differences in cognitive abilities is not clear yet, though it has been assumed that both biological and environmental factors contribute to the variation that has been demonstrated between males and females. Among the biological factors identified, differences in neurological structure and function have been pointed out (e.g., Blanch et al. 2004). Some authors have also found that hormones are associated with certain aspects of brain differentiation (e.g., Burton et al. 2005). Others have suggested that boys’ brain activity measure using functional magnetic resonance imaging (fMRI) differed from that of girls’ depending on individual cognitive process (Asano et al. 2014).

Gender differences have been attributed to environmental factors associated with changes in living conditions and cognitive stimulation taking place over time. Some studies investigating math performance in adolescents have found that gender differences favoring boys are smaller in more gender-equal societies (Guiso et al. 2008; Else-Quest et al. 2010), suggesting that gender equity positively affects girls’ math performance (Weber et al. 2014). In the United States, gender differences in mathematics performance are declining. More recent data indicate that the gender difference in math achievement has narrowed (Else-Quest et al. 2010). A study of statewide mathematics tests administered between 2005 and 2007 for Grades 2–11 did not find the increased gender gap in adolescence found with earlier data (Hyde et al. 2008). Moreover, reviewing evidence from research with infants and preschoolers, Spelke (2005) concluded that gender similarities are the rule in the development of early number concepts. However, gender differences could emerge in the high school years particularly for complex problem-solving students favoring males (Lindberg et al. 2010).

Some gender differences in the brain organization of language, including differences in connectivity, have been suggested. Evidence of cross-frequency dependence between functional networks in resting state fMRI (rs-fMRI), which

was associated to the subject gender have been found (Yaesoubi et al. 2017). Others authors utilized resting state fMRI (rs-fMRI) and graph theoretical approaches to investigate the hemisphere- and gender-related differences in the functional networks of the adult brain functional networks (Tian et al. 2011). These authors found was that males lean towards being more locally efficient in their right hemispheric networks, whereas females tended to be more locally efficient in their left hemispheric networks. It has been also suggested that male brains are optimized for intrahemispheric communication and female brains for interhemispheric communication. The developmental trajectories of males and females diverse at a young age, demonstrating wide differences during adolescence and adulthood (Ingallhalikar et al. 2014).

Conclusion

It has been frequently reported that girls present a faster language development, but boys outperform girls in the development of spatial abilities. Some authors have found that these differences are also observed during adulthood, and even during normal aging. However, the magnitude of these differences is small and several studies have been unable to support them. Recent reports have found that the gap in numerical abilities between boys and girls reported decades ago has narrowed in recent years.

Sex Differences in Commitment Skepticism

Kaitlin Richotte, Angela I. Gutierrez and
Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Definition

Women are more prone than men to show commitment skepticism bias, which is a tendency to believe people are unwilling to commit to a long-term intimate relationship.

Women are more likely than men to show a *commitment skepticism bias*, which is a tendency to believe that potential mates are unwilling to commit to a long-term intimate relationship (e.g., Haselton and Buss 2000). Error Management Theory has been used to explain these sex differences. Generally, Error Management Theory suggests cognitive biases towards either making a Type I error (believe X when X is not true) or Type II error (believe “not X” when X is true) could have evolved if one type of error, relative to the other, conferred a benefit or minimized a cost (Johnson et al.

2013). Assumptions about the intentions of mating partners could lead to one of two types of errors: believing a person would be committed to a long-term relationship when the person is not (Type I error) or believing a partner would not be committed to a long-term relationship when they are (Type II error). Because the sexes are different on the cost-benefit ratio of these errors, we would expect the sexes to be different on how likely they are to commit either error.

Because women’s minimum obligatory parental investment is higher than men’s, women can increase their reproductive success by securing a mate with ample resources and a willingness to share in parental investment over the long-term. Thus, women may be more prone to making a Type II error (i.e., show commitment skepticism) because incorrectly thinking a potential partner will commit to a long-term relationship is more costly than incorrectly thinking a potential partner will not commit to a long-term relationship. Men may not show this tendency because their reproductive strategy can maximize fitness through mate number, so incorrectly predicting a partner’s level of commitment is not as costly.

Empirically, one study found a sex difference in commitment skepticism bias (Haselton and Buss 2000), and another study found that such skepticism was only true among premenopausal women (Cyrus et al. 2011). This latter finding is consistent with Error Management Theory because mistaking a potential partner’s long-term commitment would be most costly at an age when raising offspring was likely. A third study also found results consistent with this commitment skepticism bias, where women’s ratings of men’s commitment were lower than men’s self-report commitment rating (Henningsen and Henningsen 2010).

Definition

Differences between males and females in the frequency and duration of increased tearing of

the eyes and other associated behaviors in response to internal emotional states.

Introduction

It is well established that, apart from reacting to chemical or physical irritants, adult females shed tears more often than adult males. This crying occurs in response to emotional states, sometimes induced by external events. Here, we will examine the extent of this sex difference and its possible explanations.

Sex Differences in Frequency and Duration Across the Life Span

Infants produce cries from birth but seem to weep only after 3 months of age. Because the function of signaling distress is reasonably the same throughout infant- and toddlerhood, the early absence of tears probably reflects an arbitrary anatomical or developmental age effect. Inflicting pain through the PKU test yields no sex difference in crying, but girls exhibit stronger facial expressions of pain (Guinsburg et al. 2000). Boys are somewhat overrepresented among the approximately one fifth of all children that are perceived by their parents to cry excessively. In a representative population sample, 22.7% of boys and 19.3% of girls cried excessively during the first 3 months, while 10% of boys and 6.6% of girls did so after 3 months (Wurmser et al. 2001).

Males begin to cry less during childhood. Females' values did not change across 11 to 16 years of age but were essentially constant at having cried 4 times in the previous 4 weeks, while across the same age interval, males dropped from about 2.5 to 1 times per 4 weeks (Van Tilburg et al. 2002). Among 9–13-year-old children ($M \sim 10.6$), females self-rated having cried 3.8 times and males 2.9 times in the previous 4 weeks (Jellesma and Vingerhoets 2012).

Adulthood exhibits the largest sex difference in crying. A review of 14 studies concluded that

females exhibit higher levels of all crying-related behaviors (Vingerhoets and Scheirs 2000). Studies report that females cry between 2.5 and 7.4 times more often than males, with effect sizes from around 1.0 and up. It has been suggested that changing sex roles and increased sex equality across the last 50 years would have diminished the sex differences in crying, but both frequency, intensity, and reasons for crying were similar across a 15-year period (Lombardo et al. 2001). More recent studies also report similar sex differences which replicate across 37 countries with effects sizes of 1.11 for crying proneness and 0.94 for crying frequency (van Hemert et al. 2011). Among people in their late 60s, females reported having cried on average 31.1 times in the last 12 months, as compared to 16.3 times for males (Hastrup et al. 1986). This ratio of 1.9 is less than half the typical sex ratio for young and middle-aged adults.

Sex Differences in Types of Crying and Self-Reported Reasons for Crying

Compared to males, females more often exhibit flowing tears, sobbing, and convulsive breathing, while males more often exhibit watery eyes (► “Types of Crying”). More than three times as many females than males report crying because they are angry and more than twice as many because they feel helpless. Crying and anger are in fact negatively correlated in males, but positively in females (Choti et al. 1987). In contrast, males’ crying was more than twice as often provoked by positive events, such as intense joy (Bylsma et al. 2008). Although sex differences in crying are large and consistent, the results are more mixed regarding crying-evoking situations. For example, no sex differences were found in response to highly evocative events like the death of someone close (Williams and Morris 1996).

Crying is correlated with state traits such as neuroticism and extraversion and with more transient states such as depression (► “Crying”) (Vingerhoets et al. 2009), all of which are more prevalent in females. The essence of neuroticism

is “feeling negative feelings strongly,” and it has been suggested that there is a negative aspect even to joyful crying, because it involves being overwhelmed and feeling a loss of control or because intense happiness reminds a person that they have been unhappy in the past (Vingerhoets et al. 2009).

Causes of Sex Differences in Crying

Although adult females cry more than adult males, there remains debate over why this should be the case. Social conditioning is a common explanation in the literature: crying and other emotional expression are encouraged in females and discouraged in males. Several arguments are advanced in support of these hypotheses: attitudes are less favorable toward crying males than crying females, males report more shame and discomfort when crying, sex-typical crying behaviors are associated with individual differences in masculinity and femininity (Ross and Mirowsky 1984; Lombardo et al. 2001), and the sex differences emerge when socialization and the desire to impress and attract the other sex are elevated in adolescence. However, females’ attitudes are quite similar toward male and female criers (Cretser et al. 1982), both sexes have similar attitudes when the context is taken into consideration (Labott et al. 1991), and that the effect size of the sex difference in experienced shame is only about one fifth that of crying itself (Becht and Vingerhoets 2002).

A simpler explanation is that crying-related behaviors constitute a sex-dimorphic adaptation, partly mediated by hormones. The emergence of sex differences in crying in puberty and their decrease in late adulthood is thus consistent with changes in male testosterone levels across the life span (Harman et al. 2001) and with females crying four times as much during the hormonal surge before and during menses compared to the intermenstrual period (Horsten et al. 1997; Moos 1968). A social explanation would predict that there be considerable variation across cultures and countries by chance, as social norms regarding crying are intrinsically arbitrary. It would also

predict that countries with less sex equality have larger sex differences. However, every 1 of 37 countries surveyed exhibited higher crying proneness and frequency for females, and sex differences tended to be larger in more developed and sex-egalitarian countries (van Hemert et al. 2011). The evolutionary perspective would predict that females, by making huge and self-debilitating investments in their offspring, at the same time as being physically weaker, would be considerably more prone to cry inasmuch as it attracts help and staves off aggression (Hendriks et al. 2008). Such a strategy would be further motivated by the fact that female exogamy entails dependence upon non- or distant kin (e.g., Madison 2009) and may rationally be complemented with the ability to convincingly “fake cry” in order to induce sympathy and assistance (Vingerhoets et al. 2016).

Conclusions

Females tend to be more concerned about the happiness of everyone in the group and about the feelings of others. In prehistory, this would have permitted them to bond more strongly with their children, be more loving mothers, and be better able to persuade others to assist them. It would thus be more beneficial for females to be able to more clearly express their emotions, in order to signal the need for help or support and reduce the possibility of conflict. Inasmuch as there is a degree to which crying signals a loss of control, we might speculate that it would not be an attractive quality in males in terms of sexual selection, with females being attracted to males with higher social capital (Buss 2016). Thus, the sex differences would have evolved to be what they are today under the Darwinian conditions prevalent until the Industrial Revolution, where social status heavily predicted completed fertility (Dutton and Woodley of Menie 2018, Chapters 3–4). At least, this would seem to be the most parsimonious explanation for the multifaceted sex differences in crying behaviors and attitudes toward them.

Sex Differences in Cyber Bullying

Cyber harassment; Cyberaggression; E-bullying; Electronic bullying

Definition

Cyberbullying has been defined as “an aggressive, intentional act carried out by a group or individual, using electronic forms of contact, repeatedly and over time against a victim who cannot easily defend him or herself” (Smith et al. 2008, p. 376). In all respects, save the use of electronic media, it is similar to traditional, in-person forms of bullying. All forms of bullying, including cyberbullying, are not reactive, impulsive actions, but rather are intentional, planned, and functional behaviors (Volk et al. 2014). Like traditional bullying, cyberbullying consists of direct and indirect forms including verbal, such as emailing, texting, or calling the victim to derogate or threaten them, and relational forms, such as exclusion from groups of friends, ignoring victims, or spreading rumors (Kowalski et al. 2014). However, cyberbullying can also include specific acts, such as posting embarrassing pictures or videos of others, or using deception to impersonate or pose as someone else, which fall outside of the domain of traditional bullying.

However, some investigators question whether repetition is a necessary component of cyberbullying, in light of evidence that single incidents may be harmful, especially cases that involve embarrassing or hurtful information being posted on the internet, which may be accessed by a large audience over a long, indefinite period of time (Volk et al. 2014). Furthermore, investigators have queried how the concept of a power imbalance between the aggressor and the victim – a key element in the definition of all forms of bullying – applies to cyberbullying, given that domains of power such as physical strength and popularity have clearer applications in traditional forms of bullying, including physical or relational varieties (Volk et al. 2014). Conceptual complications include whether aggressive acts using technology could be considered bullying in the absence of a clear power imbalance when anonymity afforded by pseudonyms makes these attacks difficult to defend against, and conversely, whether physical strength or popularity may affect the power balance when in-person retaliation is possible. As with other forms of aggression, Volk

et al. (2014) have concluded that aggressive acts using electronic devices should be considered cyberaggression rather than cyberbullying if an imbalance of power favoring the aggressor cannot be established.

Introduction

In line with evolutionary psychological research on traditional bullying (e.g., Vaillancourt 2013), sex differences in cyberbullying may be conceptualized with regard to theories of sexual selection and differential parental investment. In general, adolescent males are more likely to participate in bullying overall and to utilize direct forms of traditional bullying, such as physical and verbal acts, whereas females prefer using indirect, relational forms of bullying (Wang et al. 2009). According to parental investment theory, females' greater obligatory parental investment in their offspring results in their being less willing to compete for mates using risky physically aggressive strategies, in order to avoid physical harm (Vaillancourt 2013).

Sex differences in traditional bullying have also been explained with the theory of sexual selection, which is based on adaptations that have increased successful mating (Vaillancourt 2013). According to the theory of intersexual selection, the selection of mates is based on preferences for qualities that are thought to be indicative of their ability to produce, protect, and support offspring. From this perspective, females typically prefer potential mates who display strength, masculinity, and social status, as these qualities are thought to be representative of their ability to provide for and protect their partner and potential offspring. In contrast, males prefer physical ideals including youthfulness and a favorable hip-to-waist ratio, as well as sexual fidelity in potential partners, as these qualities are believed to be representative of the female's fertility and desire to mate exclusively. Thus, direct forms, such as physical bullying, would not appear adaptive for females, as it would not display preferred mating qualities and may incur large costs through exposure to retaliation. However, physical

bullying would enable males to display attractive qualities at minimal cost, as the weaker victim is unlikely to retaliate.

Relatedly, the theory of intrasexual competition indicates that same-sex individuals compete for access to resources and for desirable mates (Vaillancourt 2013). Bullying may facilitate intrasexual competition, in that physical forms may be used to make oneself look attractive in comparison to rivals, while relational and verbal forms can be a vehicle for derogating sexual competitors to reduce their appeal to potential mates. For example, females typically derogate their rival's attractiveness and sexual fidelity, whereas males tend to target their rival's physical abilities and resources (Vaillancourt 2013).

Consistent with theories of sexual selection and differential parental investment, research on traditional bullying has shown that females prefer nonphysical forms of bullying, particularly relational aggression, are slightly but significantly more likely than males to engage in relational aggression, and tend to direct relational aggression toward female peers (Vaillancourt 2013). In addition, relational aggression is associated with reproductively relevant outcomes, such as perceived popularity, dating, and sex, more strongly and consistently for females. In contrast, relational victimization reduces perceived attractiveness and dating onset only for females and places females at greater risk than males for negative outcomes, including internalizing problems and suicidal ideation and attempts, which are markers of low fitness and which reduce willingness and ability to engage in intrasexual competition (Vaillancourt 2013). Finally, females but not males who pose threats as rivals in intrasexual competition, due to being physically attractive, dressing provocatively, or having had more sexual partners, are more likely to be relationally victimized (Vaillancourt 2013).

Although research on cyberbullying from an evolutionary perspective is sparse, some findings are consistent with those for traditional bullying in suggesting that it may be used as a tool for intrasexual competition. For example, many incidents of cyberbullying occur within a dating relationship context, predominately as a result of

breakups or envy/jealousy (Hoff and Mitchell 2009). Furthermore, as with traditional bullying, youth who engage in cyberbullying in early adolescence are perceived by their peers as popular (Wegge et al. 2016).

Thus, several sex differences in cyberbullying may be predicted in light of sexual selection and differential parental investment theories, and previous evolutionary psychological research identifying sex differences in traditional bullying. Specifically, the following would be predicted: (1) females but not males would perpetrate and be victimized by cyberbullying more than physical bullying; (2) females would perpetrate and be victimized by cyberbullying more than males; (3) females would derogate rivals' physical attractiveness and promiscuity whereas males would impugn rivals' physical strength and masculinity; (4) females should experience reproductively relevant outcomes more than males as a function of cyberbullying; and (5) females victimized by cyberbullying should experience more negative outcomes than males.

Sex Differences in Cyberbullying

The evidence is inconsistent with hypothesis 1. Contrary to this prediction, research suggests that both sexes use physical bullying more than cyberbullying (Wang et al. 2009). Furthermore, similar percentages of females experience physical and cyber victimization (Wang et al. 2009). Unlike relational bullying, which is usually indirect and covert, cyberbullying may place perpetrators at greater risk of experiencing retaliation because messages sent through email, texts, and various social media are not typically anonymous. In this sense, it may not be a safer alternative to physical bullying.

Research provides mixed evidence regarding hypothesis 2. Although research in this area has been inconsistent, a recent meta-analysis found that males were significantly more likely than females to cyberbully, albeit with a small effect size ($r = 0.04$; Barlett and Coyne 2014). This finding is concordant with research showing that males and females do not differ greatly in their use

of nonphysical traditional bullying (Wang et al. 2009). Female preferences for less risky, nonphysical forms of bullying do not preclude males from taking advantage of nonphysical bullying options such as cyberbullying, especially given evidence that it yields adaptive outcomes, such as perceived popularity, for them as well (Wegge et al. 2016). Furthermore, it appears that age moderates the relation between sex and cyberbully status. Females were found participate in cyberbullying more often than males in early adolescence, with perpetration rates becoming comparable around age 11. Males become more likely to engage in cyberbullying in later adolescence (Barlett and Coyne 2014). However, a recent meta-analysis has suggested that females are more likely to be victimized by cyberbullying than are males (Hamm et al. 2015), consistent with expectations. Moreover, consistent with parental investment theory, males are more likely than females to physically retaliate in person when victimized by cyberbullying, whereas females are more likely to ignore it, avoid using technology, retaliate with negative cyber messages, or report the incident to adults (Hoff and Mitchell 2009).

In support of hypothesis 3, males using cyberbullying against same-sex rivals typically derogate their sexual orientation or physical capabilities, whereas females are likely to insult the physical appearance and reputation of same-sex rivals (Hoff and Mitchell 2009). Thus, as with relational bullying, male and female perpetrators of cyberbullying appear to target cross-sex mate preferences, possibly to reduce the appeal of rivals in intrasexual competition for mates.

Findings are not consistent with hypothesis 4, as cyberbullying predicts higher perceived popularity for both sexes (Wegge et al. 2016), providing preliminary but sparse evidence that the adaptiveness of cyberbullying is not sex specific. However, the findings of Kowalski et al. (2014) support hypothesis 5, as depression was predicted by cyber victimization in female adolescents but not males. Consistent with parallel evolutionary research on relational victimization (Vaillancourt 2013), females but not males experience internalizing problems as a result of

cyber victimization, which may reduce their willingness or ability to engage in intrasexual competition.

Conclusion

In conclusion, research indicates that there are important sex differences in cyberbullying. Consistent with evolutionary psychological theories of sexual selection, parental investment theory, and previous evolutionary studies on traditional bullying, cyber victimization was more common amongst females; the derogatory content of cyberbullying corresponds to cross-sex mate preferences, and the link between cyber victimization and internalizing problems, a marker of low fitness, is stronger for females. Conversely, cyberbullying is used by females less than physical bullying, and positively associated with perceived popularity for both sexes, inconsistent with evolutionary theory and previous research. Further research is needed, however, as there are few studies specifically examining cyberbullying from an evolutionary perspective.

Sex Differences in Death by Filicide

Stephanie Horsford
University of Bath, Bath, UK

Synonyms

Child abuse; Child murder; Filicide; Gender differences; Homicide; Parent(s); Victim

Definition

Filicide is defined as the deliberate act of a parent, stepparent, or parental figure killing their own child. Subcategories of filicide include neonaticide, when the child is killed within the first 24 h of its life by his or her parents, and infant homicide (sometimes infanticide), although in some countries the term “infanticide” only applies to the mother and has medicolegal implications.

Introduction

Filicide is a multifaceted phenomenon with various causes and characteristics (Bourget et al. 2007). It was first studied from an evolutionary perspective by Daly and Wilson in the 1980s and 1990s. As early as 1985, links were found between child abuse and the child not living with both parents. This led to an investigation of filicide, which looked at the differences between genetic parents and stepparents. Studies have shown that children are more likely to be killed by their stepparents than by their genetic parents. The literature on filicide also looks at the sex differences of those who commit filicide. Research focuses mainly on mothers, as fathers are less often considered as the perpetrators in filicide cases, and this is reflected in the amount of literature on the topic (West 2007). Sex differences in becoming victims of filicide have also been studied, although the current body of research available is very small.

Sex Differences in Perpetrators of Filicide

The main literature within the topic of filicide studies sex differences in biological parents. Most of the research has focused on the mothers and fathers individually; however, there is far more existing literature on maternal filicide than paternal filicide (West 2007).

Many studies have found that mothers commit filicide more often than fathers (e.g., Resnick 1969). This seemingly high number of maternal filicides may however be due to media bias or because neonaticides are included in some studies which considerably raises the number of maternal filicides (Bourget et al. 2007). Other research has suggested that paternal filicide is as frequent (e.g., Bourget et al. 2007) or possibly even more frequent than maternal filicide (e.g., Bourget and Gagne 2005). This is supported by Lucas et al. (2002), who found that out of 32 filicide cases within the United States Air Force, the perpetrator was male at least 75 % of the time. Bourget and Gagne (2005) found similar results after studying 77 cases of paternal filicide between 1991 and 2001 in Quebec.

In a study conducted in England and Wales, 2660 cases of infant filicide between 1974 and 2003 were analyzed, and it was found that fathers were responsible for 50 % of the cases, whereas mothers were only responsible for 31 %, with stepparents accountable for 8 % (Flynn et al. 2007). In 2013, Flynn, Shaw, and Abel conducted a very similar review looking at filicide and child homicide cases between 1997 and 2006. They suggested that fathers were responsible for a significantly higher number of filicides than mothers, with a male to female ratio of 2:1.

Mothers were found to be almost always responsible for the deaths of neonates (Resnick 1970). Mothers were also more likely than fathers to kill within the first month of their infants' lives (Flynn et al. 2007). Fathers were overrepresented in cases where the child was older than 4 weeks, with fathers being the most frequent perpetrators of filicide in later childhood (Bourget et al. 2007).

On average, victims in paternal filicide cases were generally older than those in maternal filicide cases as fathers are rarely responsible for neonaticides (West 2007).

Most research on paternal filicide have had limited samples, which doesn't allow for much generalizability (Bourget et al. 2007). One study with a larger sample showed several characteristics that seemed to occur frequently in cases of paternal filicide (Bourget and Gagne 2005). First, violence and a history of family abuse were recurrent, where more than a quarter (27 %) of the fathers had a history of repeated violent behavior. This violence is reflected in the method of killing which was consistently violent across the literature, with the most common method being a firearm (34 % of the time) and the second most frequent method being battery (22 %) (Bourget and Gagne 2005). Resnick (1969) found head trauma to be the most common method of filicide, which occurred in 38 % of the paternal filicide cases. Flynn et al. (2013) found the most frequent method of filicide to include multiple injuries, skull fractures, and shaking (43 %), with 25 % of the perpetrators having previous convictions of violence, fathers significantly more than mothers. Several life stressor factors were present preceding the offense (Marleau et al. 1999), with a large number of paternal filicides occurring after ruptures in the marital relationship (40 %) (Bourget and Gagne 2005). Being separated at the time of the crime has also been shown to be a predisposing characteristic (e.g., Lucas et al. 2002). Psychosis was found to be a common factor in men who commit filicide (West 2007) with studies showing it to be present between 30 % and 40 % of the time in several studies (30 %, e.g., in Bourget and Gagne, 2005, and 40 % in Marleau et al. 1999). Cases of filicide-suicide also had quite high rates of around 60 % (e.g., Marleau et al. 1999).

The existing research on maternal filicide is wider and looks at the crime from a variety of different perspectives (West 2007). Friedman, Horwitz, and Resnick's critical analysis (2005) indicated that although the proportion of filicide

is slightly higher among fathers (31 % compared to 30 %), the research on mothers seems to be wider, possibly because mothers are overrepresented in infant filicide cases (Bourget et al. 2007). Many overviews of filicide have focused on mothers as the perpetrators of filicide as mothers often have sole or predominant responsibility for their children. However, although there seems to be more literature regarding maternal filicide, it is a lot harder to find general characteristics that define a mother who commits filicide, as there are many different circumstances in which maternal filicide occur. Neonaticide is most often committed by mothers who are typically younger and unmarried, who have no prenatal care and who often deny and/or conceal their pregnancies (e.g., Bourget et al. 2007). The main motivator for neonaticide is most possibly the undesirability of the child (e.g., Resnick 1970). Mental illness plays a huge factor in maternal filicide; however, it is mostly present in mothers who have killed older children, as mothers who commit neonaticide present less signs of depression, psychotic illness, or suicidal attempts. Mothers who have committed filicide generally were socially isolated, full-time care providers, who may have been victims of domestic violence themselves.

Differences were found between mothers from psychiatric and correctional populations, as mothers from the psychiatric population were generally unemployed, married, used alcohol, and had an abusive history. Those from the correctional population were often unmarried and unemployed with little or no social support, had a limited education, and a history of substance abuse (West 2007). This reflects another risk factor, as mothers whose own mothers were unavailable because of alcoholism, abuse, or mental health problems were more likely to commit filicide.

Sex Differences in the Victims of Filicide

The current literature on gender differences in neonaticides has suggested no significant difference in the quantity of male and female victims

(e.g., Lucas et al. 2002). In a review of filicide cases, including neonaticides, there was an equal amount of male and female victims (Flynn et al. 2013). Analysis of the sex of victims in maternal filicide also showed no significant differences between the number of sons and daughters killed (Friedman et al. 2005). Between the ages of 4 and 15 years old, some studies have found that the victims are mostly male, whereas others have noted the number of male and female victims to be equal. Victims of maternal filicide seem to be predominantly female, and conversely, fathers seem more likely to kill their sons, especially boys over the age of 15 (Bourget et al. 2007).

Conclusion

In summary, there is still a debate as to which gender is more responsible for filicide, as there is research to support both sides. However, it does seem that the research on maternal filicide is more extensive. Research consistently suggests that mothers are almost always responsible for the deaths of neonates and are also more likely than fathers to be responsible for the deaths of younger children, whereas fathers tend to commit more filicides involving older children. Studies focusing on paternal filicide have had limited sample sizes; however, some characteristic traits have been identified. Many paternal filicides include violence and a history of family abuse, which is reflected in what is usually a violent method of killing. Relationship issues have often been a predisposing factor, such as being separated from their partner or ruptures within the marital relationship. Psychosis was also often present between 30 % and 40 % of the time. There seems to be a wider literature present regarding maternal filicide; however, this may be because of the inclusion of neonaticides in samples. Neonaticides tend to be a result of an unwanted pregnancy, and the perpetrators are usually mothers who are younger and unmarried and often deny and/or conceal their pregnancies. However,

mothers responsible for neonaticides generally present less signs of depression, psychotic illness, or suicidal attempts compared to mothers who are responsible of filicides of older children. The latter are generally socially isolated full-time care providers who were often victims of domestic violence abuse themselves.

Definition

Sex differences in the frequency and risk factors associated with homicide (as measured by standardized rates and percentages).

Sexual Selection and Male Homicide

Cross-national epidemiological analyses suggest that, in general, males are more likely to be both the perpetrators and the victims of homicide (UNODC 2013, 2018). The UNODC's 2013 *Global Study on Homicide* concluded that males comprised close to 79% of all victims and 95% of the perpetrators of homicides worldwide (UNODC 2013). Standardized homicide rates support this difference. Current data places the global male homicide rate at 9.7 per 100,000 individuals, relative to 2.7 per 100,000 for women (UNODC 2013). The gap remains even after the information is broken down by UN

regions, with some regions having higher male homicide rates than others. For instance, whereas in the Americas the rate is of 29.3 per 100,000, in Asia the rate is of 4.0 per 100,000 (UNODC 2013). The data also indicates, globally, young males are frequently the victims of homicide. The value increases from 2.0 per 100,000, between ages 0 and 14, to 16.7 per 100,000, between ages 15 and 29 (UNODC 2013). At age 30, the value drops to 14.4 per 100,000, continuing its decline throughout the rest of adulthood. These values reflect the fact that younger males are especially at risk of dying due to homicide.

Even though some perspectives (e.g., social role theory), emphasize the influence of socialization and cultural practices have on the observed sex differences in homicide rates, these perspectives do not account for how widespread this variation is across societies. Over the last 30 years, ethnographic data indicates lethal, inter- and intra-group violence is pervasive in small-scale societies, with the percentages of males dying due to conflict not only exceeding the estimates of nation-states but also occurring more frequently than female homicide (Buss 2005). Alternatively, evolutionary hypotheses not only address the persistent sexual differences in homicide across societies, but it also predicts a significant increase in male homicide in young adulthood and its subsequent decrease in later life stages. According to the sexual selection hypothesis, male intragroup lethal aggression is as an extreme manifestation of male intrasexual competition (Daly and Wilson 1990; Daly 2017). According to this view, anisogamy (the cytological variation of gametic features), the higher level of female parental investment and a wider male fitness variance (Daly and Wilson 1990), selects in favor of male risk-taking behaviors, increasing the likelihood of both perpetrating and being a victim of a homicide.

Furthermore, the positive correlation between homicide rates and indicators of wealth and income inequality, above and beyond the effects of other economic metrics (e.g., absolute poverty or economic growth; Daly 2017; Peñaherrera-Aguirre et al. 2019), supports the hypothesis that some males will

adopt violent and riskier strategies, when they have fewer resources relative to other males (Pound et al. 2009). Cross-species comparisons indicate that, in various taxa, males' ornaments used to attract females are also employed as armaments against rivals. In humans, males' access to resources serves as armament for indirect non-lethal competition and as an ornament for intersexual selection. Consequently, relatively disadvantaged males with limited access to resources are predicted to compete with other males through direct physical aggression, leading, in some instances, to homicide (Daly 2017; Peñaherrera-Aguirre et al. 2019). It is worth noting that the sexual selection hypothesis does not reject any potential cultural effects; however, from this perspective, culture operates on pre-existing, morphological, physiological, cognitive, and behavioral differences, amplifying them under varying conditions.

Homicide Rates and Individual Difference Variables

Male homicide rates additionally exceed female homicide rates because males systematically show elevations among individual difference variables predictive of risk-taking and future discounting. The study of such individual differences, which vary within and between groups, simultaneously explain how males as a group evince higher homicide rates, and why, within any particular population of males, there is a range of risk-taking, violence, and murder. Life histories are one such individual difference variable, as life histories are related to time relevant investment, and represent constellations of correlated variables evolved and developed along a continuum of *fast* and *slow*. For instance, males, on average, tend to fall on the faster end of a life history continuum, which is positively correlated with risk-taking, future discounting, and lower impulse control (Figueredo et al. 2006). Faster life histories, with their relative presentism and impulsivity, develop and evolve in response to high morbidity and mortality, both of which are acutely elevated among males in most human

populations, in large part due to contest competition. The foregoing variation among homicide rates across cultures and continents are explicable in terms of life history evolution, which tends to be faster in tropical climates (Peñaherrera-Aguirre et al. 2019).

Additionally, life histories correlate with certain personality traits, which, in and of themselves, represent individual difference variables correlative to homicide. For instance, those with faster life histories score higher in dark triad traits such as psychopathy (Figueredo et al. 2006) and, in turn, more often commit calculated murders (Woodworth and Porter 2002). Moreover, low levels of agreeableness, or high level of antagonism, were related to violence via moderating effects of trait aggression (Miller et al. 2009).

Intimate Partner Violence, Uxoricide, and Honor Killings

Although the overall frequency of homicides is higher in males than females, when the data are classified based on whether the killing was a product of intimate partner or family violence (where the perpetrator is a parent, sibling, offspring or other relatives), these sex differences are attenuated. According to 2018 UNODC report (2018), worldwide, 82% of victims of lethal intimate partner violence are women (i.e., uxoricide), relative to 18% of men dying of the same cause (i.e., mariticide). Even though this gap slightly decreased when the data are aggregated for both family and intimate partner violence (i.e., domestic violence), women worldwide are victimized at higher percentages relative to males (women = 64%; males = 36%). The report indicates that the global homicide rate of women due to intimate partner violence was of 1.3 per 100,000, with African countries displaying the highest value with 3.1 per 100,000, whereas European states lowest with .7 per 100,000 (United Nations Office on Drugs and Crime 2018). In several instances of mariticide, however, women opt for killing their partners in response to

the recurrent violence suffered in the relationship. Homicide then is the outcome of women's defensive rather than offensive aggression, further evidencing the underlying sex differences.

Concerning some of the risk factors correlated to the likelihood of lethal intimate partner violence, the partner's unemployment has been found to be one of the main predictors of uxoricide (Khaigodabi et al. 2012). Similarly, the risk increases fivefold in circumstances where the victim left the attacker for another male (Khaigodabi et al. 2012). For example, cross-national studies based on data collected in Australia, Canada, and the USA concluded that women living with their male partner experienced lower homicide rates compared with those who were separated (Wilson et al. 1997). In addition to the quality of the relationship, the presence of the victim's offspring in the household, unrelated to the attacker, is also associated with a twofold increase in the risk of lethal intimate partner violence (Khaigodabi et al. 2012). Other factors include (1) the age of the male partner (older males fearing their younger mates will abandon the relationship); (2) females displaying higher mate values relative to their mates (e.g., better education, income, status, physical attractiveness); (3) the occurrence of female infidelity; and (4) how much time has passed since the separation (women leaving abusive partners are especially at risk during the first year after the relationship ended; Buss 2005).

Two evolutionary hypotheses were developed to address the apparent evolutionary contradiction of male perpetrators eliminating a romantic partner (e.g., a risk of retaliation of the victim's kin and allies, reputation loss, increased risk of offspring death due to lost maternal investment, decreasing the likelihood of future reproductive opportunities; Khaigodabi et al. 2012). According to Daly and Wilson, uxoricide is a by-product of sexually selected traits in males. From this perspective, a malfunction of males' sexual proprietariness, meaning the desire for control over their partner's sexual behavior, is the leading cause of this maladaptive overreaction (Khaigodabi et al. 2012). Alternatively, Buss (2005) suggested that the

by-product hypothesis does not account for the occurrence of premeditated uxoricides, such as planning the murder or hiring someone to kill the victim (Buss 2005; Khaigodabi et al. 2012). For Buss, murdering a sexual partner was selected in small-scale societies as a signal directed toward future mates, indicating the costs of defection, such as leaving the relationship or copulating with other males, and as a deterrent to rival males who may intend to poach the female.

Although some states consider the honor killings of females to be equivalent to uxoricide (when the partner is the perpetrator), male consanguineal relatives or in-laws in general often commit those murders. According to the UNODC 2018 report, honor killings occur in response to the alleged reputation loss suffered by a family due to a female's behavior or condition, such as having pre-marital sexual intercourse, being the victim of sexual coercion, or eloping against their family's wishes (UNODC 2018). Risk factors associated with honor killings include the young age of the victim, as well as being single (UNODC 2018).

Conclusion

Significant sex differences exist in the frequency of homicide; most perpetrators and most victims are men. The attackers, as well as the victims, are often young males between 15 and 30 years old. Although homicide rates are higher for men, these rates vary across regions. Whereas Europe displays the lowest value, the Americas exhibit the highest. Even though several social theories provide an approximation to these differences, the sexual selection hypothesis also accounts for curvilinear pattern observed between homicide rate and age, as well the pervasive nature of this phenomenon across state and pre-state societies. This pattern reverses for lethal intimate partner violence, in which females are often the principal victims, whereas males are often the perpetrators. Sexual jealousy, infidelity, separation, and the partner's low mate value are significant predictors of uxoricide.

Emotion; Emotional communication; Evolution;
Sex differences; Social signals

Several studies seem to indicate that women have better interpersonal skills than men (McClure 2000), that women are more emotionally expressive than men in response to stimuli and during mental imagery (Schwartz et al. 1980), and that women report expressing their emotions more frequently and more intensely than men (Kring and Gordon 1998). Men and women also differ in the control they have over their emotional expressions, as when preschool girls appear to mask negative expressions better than boys when receiving an unattractive gift (Davis 1995). The goal of this section is to provide a brief overview of the main findings about sex differences in emotional communication, using the framework of evolutionary theory. In doing so, I will first clarify (1) the nature and function of emotional communication and (2) the evolutionary roots of sex differences in social behavior. Rather than an exhaustive review of the literature on sex differences in emotional communication, this section emphasizes the relevance of evolutionary theory in understanding why women and men differ in the way they produce and process emotional signals.

Evolution of Emotional Communication

A number of scholars agree that emotions are integrated psychobiological processes that have evolved to foster adaptation of organisms to their environment (Cosmides and Tooby 2000; Nesse

1990; Scherer 2005). Emotion involves the coordination of several organismic subsystems (e.g., the central and peripheral nervous systems and the muscular system) to optimize adaptation to a variety of circumstances, both social and nonsocial (Scherer 2005). In this framework, emotional communication is a set of responses that specifically address the social environment. These responses belong to the larger category of social signals, which function to influence perceiver's behavior to the advantage of the signaler (Mehu 2015) and which conspecifics use in relation to environmental cues in order to infer a variety of information about the signaler's internal states and likely intentions (Russell et al. 2003). Emotional signals are therefore essential to assess and manage the social environment, to navigate and adapt to ever complex social structures, and, ultimately, to enhance survival and reproduction.

Paradigmatic to evolutionary approaches to behavior is the idea that sex differences in reproductive strategies lead to sex differences in important aspects of social behavior such as parental investment and mate preferences (Kenrick and Keefe 1992). Sex-specific reproductive strategies likely interacted with environmental factors to shape the social environment that provided the selective pressures responsible for the evolution of social signals and emotional communication. The sex differences currently observed in emotional communication may therefore result from adaptive sex-specific signaling strategies developed by men and women to manage their social environment (Mehu et al. 2008; Vigil 2009).

For most of their evolutionary history, humans have lived in multi-male/multi-female groups in which they frequently interact with genetically related and unrelated individuals. The distribution of kin and non-kin in relation to a given sex depends on the residence pattern adopted by the species. Humans show flexible residence patterns in comparison to other primates; hence, it is hard to determine whether any of these patterns (patrilocal, matrilineal, and bilocal) is specific to our species. However, it was suggested that patrilocal has been the dominant pattern over the course of human evolution (Ghiglieri

1987), whereby males tend to stay in their native group and females tend to migrate to other groups. According to the male philopatry hypothesis, men are expected to form kin-based coalitions which aim at acquiring and defending resources but also at dealing with the selective pressures of intraspecific aggression and intergroup competition. On the other hand, female dispersion in society implies that women will mostly interact with genetically unrelated individuals and base their relationships on reciprocal altruism. These long-term and committed relationships would ensure access to the resources needed for the development of their offspring (Vigil 2009).

In order to succeed in male coalitions, men must acquire social status, dominance, and competence and, hence, display emotional expressions that are conducive to these goals, for example, anger and disgust (Stewart et al. 2015). Men are expected to be more sensitive to, and to display, emotional signals which function is to regulate social hierarchies but also to foster intra-sexual cooperative bonds. Women, on the other hand, are expected to be more sensitive to, and to display more cues of, affiliation, nurturance, and caring. Women are also expected to display emotions that promote group inclusiveness and stability (Vigil 2009). Expressions of fear, sadness, and joy are expected to be particularly important in women, as these expressions allow them to avoid conflict and increase safety (fear), to enter coalitions after a drawback (sadness), and to elicit prosocial behavior from others (joy). Does the pattern of sex differences in emotional communication observed in the literature reflect the evolutionary arguments discussed above? In the next paragraphs, I will discuss the results of both perceptual and production studies in the light of evolutionary theory.

Sex Differences in the Perception of Emotional Signals

Social psychologists have long recognized the relationship between emotions and interpersonal dimensions of personality like dominance and

affiliative tendencies (Knutson 1996). Empirical research indeed shows that perceivers' expectations about a signaler's disposition to show particular emotions are strongly affected by the sex of the signaler (Hess et al. 2005). More specifically, the perceived disposition to show anger, contempt, and disgust is associated with the male sex, whereas the perceived disposition to show fear, sadness, happiness, and surprised is associated with the female sex (Hess et al. 2005). In addition, men's perceived disposition to show anger, contempt, and disgust was partially mediated by their higher perceived social dominance and their lower perceived affiliation. On the other hand, the tendency for women to show more fear and sadness was partially mediated by their lower perceived dominance.

In a related study, the sex of the signaler had an effect on the accuracy of emotion identification by perceivers: While anger and fear (two emotions related to the regulation of hierarchical relationships) were more easily identified in male faces; sadness (an emotion related to affiliative relationships) was more easily identified in female faces (Stewart et al. 2015). Similarly, when people have to report the emotional expression of faces they have perceived for a very brief amount of time while having to perform an unrelated task, they are more likely to mistakenly attribute anger to male faces than to female faces and to mistakenly attribute happiness to female faces more than to male faces (Neel et al. 2012). These results can be taken as evidence of a bias whereby cues to threat present in the environment are attributed to individuals most likely to inflict harm (men) and cues to friendliness are attributed to individuals most likely to represent social bonding opportunities (women). Using a different paradigm, Smith et al. (2015) showed that perceivers were quicker at attributing gender to faces when these faces showed expressions that were "congruent" with cultural expectations (men show angry faces and women show happy faces). All in all, these findings support the idea that people's expectations about men and women's emotional communication styles are connected to evolved interpersonal strategies such as dominance and affiliation.

Women are considered better than men at processing emotional expressions (McClure 2000). In a perceptual study, Hampson et al. (2006) evaluate two evolutionary-based hypotheses to explain female advantage in emotion recognition: the attachment promotion hypothesis and the fitness threat hypothesis. Both hypotheses are based on the assumption that women, as primary care givers, have evolved particular abilities to recognize emotions displayed by their infants to promote their attachment and to better react to potential threats to their infant's survival. Hampson et al. (2006) found that women were indeed faster than men at labeling all kinds of facial expressions of emotions, supporting the primary caretaker hypothesis (Babchuk et al. 1985), and that the sex difference was particularly large for negative emotions, supporting the fitness threat hypothesis. This effect may be based on hardwired automatic processes, as women were also found to give significantly higher (correct) emotional ratings than men when negative facial emotional expressions were presented for less than a second (Hall and Matsumoto 2004).

Sex Differences in the Production of Emotional Signals and Their Consequences

Beyond women's perceptual advantage in the processing of emotional cues, this sex difference also seems to hold for the production of emotional signals. For example, an observational study looking at parents and child interactions revealed that girls expressed more submissive emotions, like sadness and anxiety, than boys (Chaplin et al. 2005). A meta-analysis of sex differences in smiling showed that women and adolescent girls tend to smile more than men and adolescent boys (LaFrance et al. 2003) and that this sex differences is modulated by a variety of contextual factors such as gender-based norms, situational constraints, and emotion salience. Observational studies performed in public places

revealed that sex differences in smiling depend on the person's age, on the immediate social context (who the person is interacting with), and on the type of expression displayed (Mehu 2011; Mehu and Dunbar 2008). For example, men in dyadic interactions displayed significantly higher frequencies of closed smiles than women but only when interacting with other men (Mehu 2011). In group interactions, men show disproportionately more deliberate smiles than laughs when interacting with older men, whereas this effect is not observed in women (Mehu and Dunbar 2008). Among people who engaged in friendly body contacts during dyadic interactions, women displayed more open smiles than men (Mehu 2011). Different forms of smiles may therefore be connected to different social contexts and goals, which in turn modifies the extent to which men and women differ in their emotional displays.

Not all studies find sex differences in emotional communication. In a meta-analysis of empathic and socio-emotional abilities, Eisenberg and Lennon (1983) reported that the female advantage in emotional skills is present in studies using self-reports and in studies performed in laboratory settings but tends to disappear in studies using physiological measures and unobtrusive observations of nonverbal behavior. In an observational study, Mehu and Dunbar (2008) did not find sex differences in overall rates of smiling and laughter, though the frequency of these expressions in men and women were affected by different factors, like the age and sex-composition of the groups in which they were observed interacting. As a general rule, smiling and laughter were significantly more likely to be targeted at same-sex individuals, suggesting that these expressions are used in the regulation of intra-sexual coalitions. In addition, women tended to laugh more frequently when interacting in mixed-sex groups, whereas men laughed more when interacting with other men. In mixed-sex dyads, women tended to laugh in response to men's laughter more readily than men laughed

in response to women's laughter (Smoski and Bachorowski 2003). Cashdan (1998) found no sex difference in smiling but she observed a significant negative correlation between the frequency of women smiling in the presence of strangers of the opposite sex and self-reported masculine characteristics. Cashdan (1998) also found that the more women were smiling in interactions with opposite-sex strangers were also rated as being more popular and caring, whereas these correlations were not observed in men. Therefore, although men and women may not always differ in the amount of positive emotional expressions they display, these expressions are affected by different social factors, suggesting that they have evolved under different selective pressures, as postulated by evolutionary theory.

Regarding the effect emotional expressions have on perceivers, research suggests that men and women may yield different consequences from the emotional signals they display. For example, ambiguous expressions (representing a blend between sadness and anger) are rated as sadder when posed by a woman than by a man but are rated as angrier when posed by a man than by a woman (Plant et al. 2004). The same study reported that female faces showing ambiguous expressions were rated more positively than male faces showing the same expressions. The level of affiliative intentions attributed to a smile is also higher when the person smiling is a woman than if it is a man (Hess et al. 2000). Similarly, female smiling faces appeared to have a more positive impact on perceivers' evaluations of personality characteristics than male smiling faces (Mehu et al. 2008). In an observational study, boys and girls were found to be rewarded differently by their parents for expressing evolved sex-specific emotions, and differential responses to some of these expressions influenced their subsequent use in social interactions (Chaplin et al. 2005). Therefore, the consequences for expressing a particular emotion are different for men and women, and these consequences may feedback

on the future use of these expressions in social relationships. Such feedback loops between sex-specific emotional expressions and the social environment may reflect flexible patterns of adaptation whereby people learn whether a given strategy is likely to work in a specific social context.

Conclusion

All in all, the findings reported above are compatible with the evolutionary hypothesis that women and men use emotional communication for different reasons and that women who are prosocial and caring display positive emotional expressions which promote group inclusiveness (Vigil 2009). Regarding socio-emotional skills, men may be better equipped to deal with hierarchical and competitive interactions, whereas women may be better equipped to deal with prosocial interactions. A few reservations can nevertheless be added to these conclusions. First, the vast majority of studies in the field have not directly addressed evolutionary hypotheses, which decreases the validity of the interpretations made above. Second, most studies are performed using a perceptual paradigm in which social context variables are not always taken into account. Third, past research usually focused on six to eight basic emotions with an overrepresentation of negative emotions, as joy is typically the only positive emotion in the set. In addition, using patrilocality as an evolutionary model to represent the social structure in which emotional communication has evolved (e.g., Vigil 2009) may not accurately depict human evolutionary history. Alternative predictions could be derived by using other models of human social organization (e.g., matrilocality or mixed residence patterns), in which a larger variety of socio-ecological variables are investigated. Finally, future investigations of the social contexts in which emotional communication strategies are adaptive should also consider the interaction between biological sex and sociocultural roles attributed to men and women in a given culture.

Sex Differences in Human Mate Preferences (Buss, 1989)

Gregory Louis Carter
York St John University, York, UK

Introduction

Evolutionary psychology owes its origins to a number of eminent scientists. Among them are Charles Darwin (1871), Ronald Fisher (1930), Robert Trivers (1972), George Williams (1975), and Donald Symons (1979). Many more eminent researchers have emerged since, influenced by their work, following in their pioneering footsteps. David Buss is one such example. His seminal 1989 paper “Sex Differences in Human Mate Preferences” evolved from this rich and varied backdrop of scientific endeavor and has informed, enlightened, inspired and occasionally provoked readers ever since. This paper is the focus of the present chapter.

Overview

This chapter will begin by providing an overview of the main aspects of the original 1989 paper and then consider some of its limitations. It will subsequently focus on more recent research, in how it relates to the paper, and finally conclude, reflecting on its overall impact and importance.

Buss’ dedicated work on evolutionary theory began in 1981, at Harvard University; a year later, he commenced the study that would become the one discussed in this chapter (Buss 2008, p. xvii). It is indisputable that “Sex Differences in Human Mate Preferences” (Buss 1989) has had a profound impact on psychological research and researchers: at the time of writing, it has been cited approximately 4,000 times (Google Scholar). It features “37 samples, drawn from 33 countries, located on six continents and five islands (total $N = 10,047$)” (Buss 1989, p. 1). Though not without issue, its

scale – and its content – is impressive. Its premise and the questions it poses, however, are comparatively straightforward.

The primary purpose of Buss (1989) is to explore the characteristics that humans find attractive in potential mates. Five candidate values were considered: earning capacity, ambition/industriousness, youth and physical attractiveness, and chastity (as measured here, equating to virginity). Buss made predictions as to how each sex might differentially value each characteristic – namely, that women, more than men, would value earning potential and ambition. Conversely, men, more than women, were predicted to place greater value on (relative) youth, physical attractiveness, and chastity.

Preferences for these attributes were hypothesized to have evolved over generations, impacting both current and ancestral mate choice. As a result, they affect inter- and intrasexual selection (i.e., opposite-sex preferences and same-sex competition, for access to desirable mates). Mate choice is not random; it is underpinned by nonconscious influences relating to the likelihood of successful reproduction, for the individual organism and, should they succeed, their offspring in turn (see, e.g., Miller 1998). At the time Buss’ (1989) research was published, little was known as to which specific characteristics were preferable, to which, if not both sexes, and whether preferences might be consistent across cultures.

Trivers (1972) previously argued that sexual selection is driven by the investment that males and females differentially make into producing and raising offspring. In humans, females typically make the greater investment, from the gamete (i.e., ova) level, through to costly gestation and nurturing periods. Thus, Buss (1989) posited the potential for a male to provide resources – via their earning potential and ambition/drive – would be a germane factor in females’ preference for a specific partner. High levels of these characteristics would enhance a female’s, and any offspring’s, chances of survival and ongoing reproduction.

For males, Buss (1989) argued potentially costly investment in a mate maybe affected by

their likelihood of fertility and/or future reproductive value, influencing the potential for conception(s) (see also Williams 1975). In human females, fertility peaks in the mid-teens and declines thereafter, typically to menopause. Age is therefore a germane factor, affecting male mate preferences: simply put, men who did not prefer fertile females would limit their reproductive success. Physical attractiveness is inexorably linked to this issue. Features associated with youth (e.g., good hair and skin, full lips) suggest reproductive capacity and are thus typically found attractive by males. Buss argues that, while there may be cultural variation in specific preferences (e.g., body shape), an attraction on the part of males to these features should be species typical. Finally, in respect of chastity, males who value chaste females are likely to have greater paternal certainty than those who are more indifferent toward a partner's sexual contact. Such males may also more likely engage in tactics that maintain a partner's chastity, such as mate guarding (Platek and Shackelford 2006). The absence of this preference would increase paternal uncertainty and the potential for unknowingly investing in another's offspring/genes. Maternal certainty, by contrast, is never in doubt, explaining the hypothesis that a preference for this characteristic will be stronger in males than females.

The methodology (Buss 1989, p. 5) consisted of two instruments, translated as necessary. The first gathered demographic data from participants asked participants to state their preferred age for marriage, desired age difference between themselves and their spouse, whom they desired to be older, and number of desired children. Participants were also asked to rate 18 characteristics on a four-point scale; among them were the target variables of "good financial prospect," "good looks," "chastity" (virginity), and "ambition and industriousness." The second instrument featured 13 characteristics that participants were asked to rank from 1 to 13 in terms of desirability; these included "good earning capacity" and "physically attractive."

In testing hypotheses regarding males' (youth; attractiveness; chastity) and females' preferences (ambition/drive; earning potential), results reading women's preferences indicated that in 36 of the 37 samples, predicted sex differences emerged for earning potential. Buss later queries whether this reflects an ability to provide for offspring, or an increase in status, protection, and, in general, "good genes" (per Trivers 1972). For ambition/industriousness, 29 of 37 significant sex differences emerged in the same, predicted direction; in one sample (Zulu participants), results were significant in the opposite direction (higher male preference). Buss (1989) notes that his collaborator (unnamed) suggests this is a cultural issue, whereby Zulu women are expected to build houses, fetch water, and complete other laborious undertakings.

For hypotheses regarding males' preferences, beginning with age, in all 37 samples, males reported a significant preference for younger partners; these were the largest or strongest findings across the study, showing significance <0.0001 in all cases. Additional demographic analyses suggested the mean age for marriage, across all participants, was 24.83 years old, close to peak female fertility, though not reproductive value (Females also reported a preference for older male partners, in all cases.) Buss (1989, p. 9) additionally reports analyses of actual age at marriage compared with self-reported preference, where applicable, briefly put actual age of marriage seem to validate self-reported preferences, and support the evolutionary proposal that males prefer and choose females displaying cues regarding high reproductive potential. For males' greater preference for physical attractiveness (per "good looks"), 34 of 37 samples showed significant results in the predicted direction; the other three (India; Poland; Sweden) showed significant male preferences for the ranked variable "physically attractive."

Finally, regarding males' greater preference for "chastity" (virginity), samples showed great variety. Ultimately, 23 of the samples returned significant results in the expected direction. All Eastern

European and most Asian samples reported a significant preference; most Western European, Canadian (English and French), New Zealand, Chinese, Indonesian, and white South African samples did not report a significant preference. Buss (1989) subsequently notes that, unlike the other variables, chastity cannot be directly observed *per se*, but concludes that whether this may bear relevance to the present results is speculative and reflects gaps in contemporary knowledge.

Across results outside of the chastity characteristic, even where results did not achieve significance, in the majority of cases, the direction of the results was aligned to the hypotheses. Ultimately, therefore, each of the predictions made by Buss (1989) was supported, though with only moderate support regarding a female preference for ambition/industriousness.

Limitations and Reflections

Despite the generally strong support for the hypotheses, the study is not without its flaws. Buss (1989) himself acknowledges several. The first is that the samples are not representative of the populations of each country, citing underrepresentation of rural populations. This may well be an issue; a Bolivian study (Schvaneveldt and Huler 2012; $N = 500$, 50% rural) found a number of significant “deal breakers” for potential long-term partnerships, several of which would fall under ambition/industriousness, chastity, or physical attractiveness categories (the latter two include direct questions about these issues); all were less important to rural participants.

In addition, Buss (1989) raises the issue of arranged marriages within some cultures as a potential confound for the evolution of mate preferences. Available evidence suggests this bears consideration. Buunk et al. (2008) explored parent-offspring conflict and found this was greatest where disagreements emerged over issues regarding a mate’s heritable fitness or parental investment indicators. Buunk et al. also echoed a call (citing Buss and Schmitt 1993) for

researchers to explore the implications of constrained mate choice – i.e., in opposition to preferences. Regarding the somewhat unexpected findings as to variation across cultures in males’ preferences for female chastity/virginity, Buss (1989) notes that assorted cultural reasons for this unanticipated finding, but not specifically, or at length.

Another candidate limitation was that sex distributions overlapped, despite significant mean differences. This may reflect an absence of sex differences across multiple items; the issue of similarity in preferences across males and females is explored more below (cf. Li and Kenrick 2006).

A suite of issues acknowledged by Buss (1989) surrounds the methodology of the study. There are problems associated with using a stand-alone self-report format, which presents numerous issues (such as socially desirable responding), as well as the use of some single items, compared with item clusters (per Nunnally 1978).

Beyond Buss’ (1989) own reflections, one could argue that the paper focuses on a limited range of factors (i.e., five). Indeed, there is a vast range of human characteristics that have been argued or found to be desirable, beyond the five featured in the original paper. Among these are intelligence (i.e., “*g*”; Miller 2000), and female body odor, such that it may indicate menstruation/high fertility (Kuukasjärvi et al. 2004). Other studies have reported specificity in some characteristics that Buss measured: Jonason et al. (2012), for example, found that female preference for males possessing resources was higher when the target had “earned” rather than inherited or embezzled them. Undoubtedly, a broader range of characteristics could have been studied; however, Buss could – understandably – have only ever assessed a fraction of “human mate preferences.” It bears noting, however, in respect of influence, that each of the citations above directly refers to Buss.

While the geographical scope of Buss (1989) is vast, sample sizes are considerably uneven. The

samples from the USA and Germany, for example, are by far the largest (USA, $n = 1,670$; Germany, $n = 1,083$) and dwarf samples from the African continent (South Africa (white and Zulu), $n = 228$; Nigeria, $n = 172$; Zambia, $n = 119$). Samples from Arabic cultures are also represented only by Palestinian ($n = 109$) and Iranian ($n = 55$) participants. While this is an underrepresentation of some specific communities, a considerable proportion ($>50\%$) of Buss' sample is not from "WEIRD" demographics (i.e., Western, Educated, Industrialized, Rich, and Developed; Henrich et al. 2010). Importantly, particularly in relation to the results discussed above in relation to males' value regarding chastity, this highlights "Western" versus other demographic preferences. The recruitment of samples of this nature remains an ongoing issue in psychological and some evolutionary psychological research; Buss is, in this respect, an early adopter.

In addition to the above, there are some issues surrounding this paper's interpretation. This is not Buss' (1989) fault, as the current paper does not reduce its conclusions thusly, but it can be (and often is) misinterpreted as "men want attractive women; women want wealthy men," which is misogynistic. Regrettably, this is frequently the way it is interpreted, or broadcast, by media outlets, even when researchers cite apposite theory (e.g., Ting 2015, citing Buss (1989) and Fales et al. (2016)). In fact, Buss directly states that "male and female preference distributions overlap considerably, in spite of mean differences" (Buss 1989, p. 13).

From Li and Kenrick (2006), it is clear that there is variation in human mating preferences based on short- or long-term scenarios, which Buss (1989) does not distinguish between, methodologically. Rather than sex differences, Li and Kenrick found a similar preference for physical attractiveness in men and women in the case of a short-term scenario and for kindness, intelligence, and general well-roundedness in a long-term one. Some sex differences remained – resources and attractiveness were more important to women and men respectively in the long-term scenario, but

this paper highlights the relevance of context to mate preferences.

Looking at socioeconomic status (SES) preferences, Greitemeyer (2007) found that males actually reported a preference for women with lower resource provision (by extension). The female preference for men with higher SES (per Buss 1989) remained, but Greitemeyer notes that the strength of the preference varied according to short- (weaker) or long-term contexts. Greitemeyer also reported that mediation analyses showed that males' preference in this respect was mediated by candidate partners' educational levels (and by extension potentially greater SES/independent resources), with males perceiving highly educated women as less likeable and faithful. This may reflect a response to recognizing where males' own mate value is lessened.

Eastwick and Finkel (2008) also found no evidence for sex differences in preferences for attractiveness or earning potential in reports based on real-life encounters, compared with Buss' (1989) use of pen-and-paper self-reports. Context and methodology therefore both appear pertinent to fully understanding sex differences/similarities.

A final suite of proximate mechanisms (social, psychological, physiological, and ontogenetic) that may contribute to the results in this study is proposed by Buss himself (1989). Buss flags genetic differences, sensory preferences, socialization differences during development, and structural differences at a societal level, such as patriarchal issues that may limit female access to resources – see, e.g., Carli and Eagly (2001) – as candidates.

Ultimately, several of these issues can be at least partially attributed to Buss (1989) being a "starting point," or catalyst, in many respects, with subsequent acknowledgement that preferences are highly complex (see, e.g., Buss 2003; Li and Kenrick 2006). Buss (1989), instead, represents a milestone – and not simply in evolutionary psychology but in the field of psychology as a whole.

Conclusion

While not without issue, particularly in regard to culture, the considerations of the relationship between cultural variations in sex differences Buss (1989) reports are novel, and generally presented well, conceptually. Buss also acknowledges that “currently unknown are the cultural and ecological causes of variation from country to country” (p. 13). Equally, while methodological issues are present, which Buss acknowledges, the paper breaks new ground and raises important issues. The results fundamentally support the proposal that males and females have developed, over evolutionary time, in response to different issues regarding reproduction (such as lengthy gestation, for females, and wasted effort, on the part of males) and reproductive success.

Moreover, the results have implications for human intersexual competition, and abandoning – at the time Buss (1989) was writing – notions of “choosiness” being exclusive to females (per Buss 1988; Darwin 1871). The proposal Buss (1989) makes in the conclusion regarding the need to test hypotheses regarding human and particularly female intrasexual competition has been taken forth by researchers such as Campbell (2004, 2013) and Fisher and Cox (2011).

In addition, Buss (1989) has undoubtedly (per the volume of citations) had a substantial influence. More researchers have adopted an evolutionary perspective as a result; more undergraduates and postgraduates will have been exposed to evolutionary theory as a consequence. The effect of this cannot be underestimated – indeed, Buss dedicates his “New Science of the Mind” textbook, in part, to all students of evolutionary psychology, past, present, and future (Buss 2014). Individual researchers (Jonason, personal communication) who have themselves had considerable influence have even been drawn to psychology, specifically evolutionary psychology, as a discipline,

due to Buss (1989), and its successor, the book “Evolution of Desire” (Buss 1994, 2003).

Perhaps most importantly, the paper has been a major catalyst in prompting researchers to undertake large-scale, cross-cultural projects that attend issues germane to humanity’s evolved psychological mechanisms (e.g., Schmitt 2005 Sorokowski et al. 2011). Simultaneously, it has had a trickle-through influence on smaller-scale evolutionary studies that consider how ecological and environmental variation(s) may explain specific competencies and traits in humans, within (Sorokowski and Sorokowska 2012) and beyond sexual preferences.

Where ideas that emerged from Darwin’s (1871, 1968) works lay dormant for decades, due to the controversy that surrounded them, Buss (1989) was among the first to empirically test their hypotheses in relation to human mating, certainly on such a scale. Moreover, Buss’ paper is one of the first to attempt to assess, on such a scale, what would now be called non-“WEIRD” individuals. These are perhaps the greatest strengths of Buss (1989); in both cases, it has proven a highly potent catalyst for myriad researchers since its publication.

A decade ago, Penke et al. (2007) observed that “with the growing acceptance of evolution as a meta-theory for psychology, more and more personality psychologists are trying to conceptualize personality within an evolutionary framework” (p. 553). Evolutionary psychology has continued to progress since then; Buss (1989) was a substantial part in the discipline arriving at this point and will no doubt continue to play a role in propelling it forward.

Sex Differences in Inferring Sexual Interest

Connor M. Jackson and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Definition

Men, likely due to asymmetrical costs, are more likely to incorrectly infer sexual interest from women than incorrectly infer sexual disinterest. This tendency is known as the sexual overperception bias.

Cross-List: Error Management Theory

Men appear to have a greater tendency than women to infer sexual interest from members of the opposite sex. For example, men are more prone to perceive women's friendliness as sexual interest (e.g., Levesque et al. 2006). Men's tendency to erroneously perceive sexual interest from women is known as the sexual overperception bias (Kohl and Robertson 2014). This general pattern has been replicated across many studies using different methodologies, suggesting it is a robust effect (e.g., Haselton and Buss 2000; Henningsen and Henningsen 2010), and some research has also looked at the moderating effects of interest in short-term mating and attractiveness on overperception bias (Perilloux et al. 2012).

Haselton (2003) applied Trivers' theory of parental investment to explain sex differences in inferring sexual interest. According to parental investment, the sex with lower minimal obligatory parental investment is less choosy in their mating partners because they can increase reproductive success through mate number, resulting in increased intrasexual competition for mateships. The sex with the higher minimal obligatory parental investment is more choosy in their mating partners and are unable to increase reproductive success through increasing mate number. Since

men have lower minimal obligatory parental investment, missed opportunities for copulation would be more costly than time and energy expended on unsuccessful mateships, so theoretically it would benefit men to err on assuming members of the opposite sex are sexually interested in them.

Error management theory has been used to explain why men are more likely to incorrectly overperceive than underperceive sexual interest (Haselton and Buss 2000). Generally, error management theory suggests that people may have evolved a cognitive bias toward making a false positive (thinking X is true when it is not) or a false negative (thinking X is not true when it is) when one error either confers a stronger net benefit or minimizes costs. This model can be applied to perceptions of sexual interest, because people can be wrong in one of two ways: false positive is thinking a person is sexually interested when they are not; and false negative is thinking that a person is not sexually interested when they are. Since men can increase reproductive success through mate number, such a false negative would impose a greater cost than a false positive. Thus, men may have evolved a tendency to err on the side of perceiving sexual interest, even if incorrect. Since women cannot increase reproductive success through mate number, a false negative is not as costly, and so a sexual overperception bias does not appear to serve a function among women. Data support these hypotheses (e.g., Haselton and Buss 2000; Henningsen and Henningsen 2010).

Sex Differences in Intimate Partner Violence

Krystal D. Mize

Florida Atlantic University, Boca Raton, FL, USA

Synonyms

Domestic violence; Gender differences; Partner violence

Definition

Intimate partner violence is physical, sexual, or psychological aggression between intimate partners. Traditionally, men have been portrayed as the perpetrators of IPV with women only engaging in partner-directed violence in self-defense. More recent research has demonstrated that patterns in IPV may be more gender symmetric in some cultures. A context-sensitive model of violence serves to explain how evolved sex differences can be moderated by contextual cues.

Introduction

There has been some debate about the gender patterns in intimate partner violence (IPV). Early research suggested that men were the primary perpetrators of IPV, and when women were aggressive, it was done in self-defense (e.g.,

Dobash and Dobash 2004). However, much of the research on IPV has reported a more symmetrical pattern of IPV perpetration between the sexes (e.g., Bookwala et al. 2005). Other researchers have reported asymmetry in IPV rates between the sexes with the rates of female-to-male acts being higher relative to male-to-female rates (Archer 2000, 2006). Both of the latter findings are in conflict with the traditional view of gender asymmetry for IPV perpetration being in the male direction. To fully understand the diverse findings on gender patterns in the IPV literature base, differences in operationalization and methodology across studies need to be reviewed. This entry will include a brief overview of IPV and the range of methods used to assess it. Finally, an overview of the use of aggression in the context of intimate relationships within an evolutionary psychological framework will be examined.

Intimate Partner Violence Definition and Typology

Intimate partners include both current and former romantic or sexual partners such as spouses, domestic partners, girlfriends, or boyfriends. IPV has been documented in both same-sex and opposite-sex relationships, but this entry is focused on relationships involving opposite-sex relationships. IPV generally refers to physical, sexual, or psychological aggression between intimate partners and also may include stalking (Breiding et al. 2015). Physical forms of IPV include acts of hitting, scratching, kicking, biting, choking, shoving, or throwing victims as well as other forms of physical violence. Sexual violence includes rape and other unwanted sexual contact. Examples of stalking include watching, following, or contacting a victim. Psychological IPV involves name calling, mind games, and other intentions to harm another person mentally or emotionally.

Intimate Partner Violence Assessment

Much of the data on IPV has been collected through reports to law enforcement or domestic violence assistance agencies, examining homicide data, and through self-report surveys. Sex differences in rates of IPV vary as a function of which

methodology is used to collect the data. Data from law enforcement or domestic violence assistance agencies suggest that men are more likely to be perpetrators of IPV. However, it must be noted that there may be some reporting bias to these agencies. Given our societal gender roles, male-directed aggression from women is not deemed as troublesome as is victimization of women. Further, women are more likely to have increased severity of injury as a result of IPV incidents (Archer 2000) and consequently are more likely to seek treatment or be referred to domestic violence agencies. It follows that only a portion of IPV incidents are included in the data provided by law enforcement or domestic violence assistance agencies. However, homicide data, which is less prone to reporting bias, also suggests that men are more likely to be the perpetrators of IPV. For example, reports from the FBI suggest that men are the perpetrators in nearly 75% of all intimate partner homicides. This supports the view that there is gender asymmetry in IPV perpetration. Nonetheless, the analysis of self-report measures of IPV has resulted in contradictory findings about the gender patterns in IPV. Hamby (2016) speculates that this may be due to the characteristics of the scales used and the populations studied, but the suggestion of female-perpetrated IPV does need consideration.

Causal Factors of Intimate Partner Violence

Psychologists suggest that behaviors are a result of both proximate and ultimate causes. Causal variables that are thought to be immediately related to the occurrence of some behavior are proximal. Underlying the various proximate causes for behaviors are the more distal or ultimate causes. Both levels of analysis are important to understanding IPV.

Proximate variable: Abuse history.

Researchers have proposed that a number of proximate variables are involved in IPV. For example, one of the strongest predictors of becoming involved in violent intimate partner relationships is being exposed to violence during childhood (Widom 1989). Large reviews have revealed consistent support for this intergenerational transmission of violence theory (e.g., Hotelling and

Sugarman 1986), but more in-depth research has revealed gender differences in the effects of past abuse (Langhinrichsen–Rohling et al. 1995). Having a history of abuse in the family of origin is related to male perpetrators not only having less likelihood of injury but also using more severe violence in marital conflicts relative to women with abuse histories. Further, who the perpetrator was in the childhood abuse made a difference in the role men and women took in abusive relationships. Violence from mothers was predictive of being an IPV perpetrator as an adult, whereas being victimized by a father was related to being a future victim. In other research, Ansara and Hindin (2009) found that having witnessed violence between their parents as a child was predictive of wives being the sole perpetrator of IPV as well as their being involved in relationships characterized by reciprocal perpetration patterns.

Kaukinen et al. (2015) also found evidence that abuse in the household during childhood was associated with experiencing IPV in adulthood. However, they found that race and gender moderated this effect. Caucasian women who did not have a childhood history of family violence were at a significantly lower risk for dating violence than non-abused African American women, but this racial difference disappeared in women from abusive homes. Further, Caucasian men who did not have a childhood history of violence exposure were found to be more likely to be involved in mutually violent relationships relative to African American men. For those men who were abused in childhood, this pattern was reversed. The above findings highlight the need to consider how proximate variables may interact with one another as causal factors of violent behavior in relationships.

In addition to having a history of childhood abuse, past abuse in the current intimate relationship has been implemented as being a contributing factor to partner violence. In fact, it has been long believed that women's use of IPV is used as a self-defense mechanism within the context of ongoing abuse by male partners (e.g., Dobash and Dobash 2004). Swan and Snow (2002) studied 108 women who had been identified as using violence against their male partners. In support of the self-defense hypothesis, they found that

only 12% of the sample could be classified as being the aggressor in the abusive relationship. The remainder of the sample reported violence toward their abusive male partners (34%) or were involved in mutually combative relationships. Of the latter group, the male partners were found to be more in control of the relationship violence. Overall, about 75% of the sample of women reported that their use of violence was in the context of self-defense against ongoing violence from their male partners. Women also report that they use violence against male intimate partners out of fear for their children (e.g., Johnson and Hotton 2003). Although it is not an excuse for engaging in violence, being at risk for being victimized by their male partners is an important contextual factor to be considered in women's IPV experiences. Further, the view that woman's use of violence against men is often self-defensive in nature has colored how women's use of violence against men is viewed relative to male-/female-directed violence.

Proximate factor: Culture. Much of the research on IPV has taken place in the United States. A review of the literature on this topic reveals that patterns of IPV in the United States may be unique in that men are more violent in some other countries. Men's and women's levels of violence are likely to covary as a function of social attitudes and environmental pressures. For example, Adinkrah (2009) reports low rates of women killing their husbands in Fiji where male-perpetrated violence against women is condoned and women are expected to comply with patriarchal control. Similarly, in the Philippines, when husbands were dominating and controlling, they were more likely to be the sole perpetrator of IPV (Ansara and Hindin 2009). Hitting women is less acceptable in the United States where patriarchy is less prevalent and American women are also more likely to fight back.

In an international review, Krahé et al. (2005) found that sex differences in victimization varied across cultures. However, similar to the contradicting reports of gender patterns found in literature from western samples, they found conflicting reports of gender patterns in IPV. Across cultures, the prevalence of physical

violence perpetration was about even for men and women with incidence rates showing asymmetry between the sexes but with no clear direction. Another meta-analysis of 16 countries revealed that gender patterns of victimization were correlated with gender empowerment and the individualistic-collectivist dimension of the cultures (Archer 2006). In countries with higher levels of gender equity and individualism, women were found to use more physical aggression toward their intimate partners. In a second analysis, Archer found that sexist attitudes and social acceptance of abuse of women were related to women's victimization rates and inversely related to gender empowerment. Together, these findings suggest that IPV typology varies cross-culturally as a function of social attitudes.

Ultimate factor: Evolutionary history. Studying the proximate factors involved in IPV, such as socioeconomic variables, gender roles, and cultural norms of aggression, has provided researchers with a plethora of information about risk factors for and sex differences in partner violence. To gain a comprehensive understanding of the gender patterns in IPV through, researchers need to consider the ultimate causes of behavior as well. Evolutionary theories provide a framework for examining the sex differences and similarities found in the IPV literature.

Both sexes face the evolutionary problem of finding and maintaining intimate partners. Parental investment (PI) is a constituent of sexual selection theory (SST). Trivers (1972) identifies PI as the expenditure of attention and resources that serve to increase the likelihood of an offspring's survival and reproduction at the cost of other components of fitness for the parent. Together, PI and SST dictate that men and women benefit from sex-specific mating strategies as a function of their obligatory parental investment. Men and women differ in their reproductive investment, with women investing more in offspring than do men. From an evolutionary perspective, being reproductively successful takes more time and energy for women relative to men. Given the heavy cost for women, it benefits them to limit men's reproductive access and to be selective in their mate choices. Conversely, the cost of reproduction is lower for men

relative to women, and therefore they increase their reproductive rewards by mating with multiple partners. This evolutionary arms race between the sexes results in high competition between men for access to quality mates. Aggression serves as one of many adaptive strategies that men use as they engage in this intrasexual competition. Although women may benefit from the use of aggression as well, there is reason to believe that women are less likely to resort to risky competition strategies than are men.

Aggressive encounters put people at risk for serious injury and can be lethal. Since women invest more in their offspring, we should expect that it may be more detrimental to children to lose their mother's relative to their fathers. Research has supported this proposition. Sear and Mace (2008) found that across 22 cultures, the death of a father had almost no effect on the survival of offspring, but the loss of a mother significantly reduced the likelihood of children's survival. Evolutionarily speaking, engaging in aggression is more costly to women and their children than it is for men. Campbell (1992) suggests that the evolutionary imperative for mothers to survive results in females favoring low-risk, indirect, or verbal aggression rather than physical aggression. However, adaptive strategies are flexible and therefore are sensitive to context. Physical aggression may serve as a mechanism for survival and reproductive success in some situations.

In general, it has been found that men engage in aggression more often than women, and evolutionary psychologists have suggested this is related to the different reproductive strategies of the sexes. However, there is some debate about sex differences in aggression between partners in the context of domestic relationships. Traditionally, men have been portrayed as the perpetrators of IPV, but there is evidence that men and women use aggression at similar rates in the context of domestic relationships (Bookwala et al. 2005). In fact, in a meta-analytic review, Archer (2006) found that women were more likely than men to engage in aggressive acts against their partners. Reports of domestically violent women have been problematic for social and evolutionary scientist alike.

Early explanations for the phenomena centered on portraying female-initiated IPV as a self-defense strategy against male-initiated abuse (e.g., Dobash and Dobash 2004). Counter to this suggestion, Stets and Straus (1992) reported that even when violence against nonviolent men was considered, rates of women's use of aggression in IPV cases remained higher than male rates. Controversy surrounding which sex is more aggressive in IPV situations or if the violence is mutual may be due to how aggression is conceptualized in research on the matter. Early reviews of the IPV literature focused exclusively on physical aggression, a male-dominated form of aggression. Sex differences are found when the behavioral expressions of aggression examined are physical acts, but when indirect aggression is considered, the sex difference disappears (Archer 2004). It should be noted that men are more likely to kill their partners (e.g., Langan and Dawson 1995) or seriously injure them in sublethal intimate partner conflicts though (Bookwala et al. 2005). Therefore, conflicts that escalate to a physical level appear to have more severe consequences for women, and therefore an explanation for why they may resort to physical aggression in some circumstances is needed.

Interaction of Proximal and Ultimate Causation

Proximate and ultimate causes of behaviors do not operate in isolation. Goetz (2010) has suggested that the use of violence is a context-sensitive strategy for solving some evolutionary problems. Both sexes likely benefitted from this solution in some context in our evolutionary history, and therefore Cross and Campbell (2011) suggest that the mechanism underlying aggression is the same for men and women. However, since the costs of aggression are higher for women, they may be less likely to use riskier forms of aggression. Consistent with this proposition, the research demonstrates that women use more indirect forms of aggression than they do physical aggression. Women do resort to physical violence sometimes though.

An examination of the role of emotion in aggression may offer an answer as to when women may use physical violence. Both anger and fear have been associated with aggression. Further, Winstok (2007) postulated that anger motivates aggression while fear serves to inhibit it from occurring. In a meta-analysis, Archer (2004) found no sex differences in anger, but there is evidence of differences in frequency and intensity of fear across the sexes. Cross and Campbell (2011) suggested that the sex differences seen in aggression levels are explained by women's higher responsivity to fear. The authors go on to argue that the inherent release of oxytocin that accompanies intimate partner interactions also serves to reduce fear. In situations where fear reactivity has been reduced, the chance of violence being used by men and women may equalize. This proposition serves to offer an explanation for why IPV is the one context for violence in which similarities may be expected between the sexes. In cultures where gender empowerment is higher and women's use of violence against men is condoned, we would expect to see even more evidence of this, a proposition that is supported by the findings in the literature (e.g., Archer 2006).

Conclusion

Conflicting findings in the IPV literature may be a result of differences in operationalization and a lack of validity of some of the measures used in IPV research. Viewing violence as being a result of a context-sensitive problem-solving mechanism explains why so many proximate variables are associated with IPV. In addition to acquiring aggressive schemas through observation, individuals who have been exposed to violence in childhood may have altered sensitivity levels to violence than those who did not experience abuse in their family of origin. Different ecological factors also can serve as cues for using violence more frequently or aggressively in some cultures. Finally, a context-sensitive model of violence serves to explain how evolved sex

differences can be moderated by contextual cues such as gender empowerment.

Sex Differences in Jealousy

Jaroslava Varella Valentova

Department of Experimental Psychology, Institute of Psychology, University of São Paulo, Cidade Universitária, São Paulo, SP, Brazil

Synonyms

Sex differences in sexual versus emotional jealousy; Sexual versus emotional infidelity; Sexual versus emotional jealousy

Definition

Sex difference in jealousy is any quantitatively or qualitatively significant difference between males and females in any jealousy-related measure of any effect size, despite of an overlap on the population curve.

Introduction

Jealousy is an affective state that occurs in response to a perceived, potential or real, threat to a social relationship caused by a third party. Romantic jealousy is specifically aimed at securing and maintaining the current partner and relationship and/or competing with actual or potential rivals. An extra-pair involvement poses risks to the current relationship, and thus both parties are facing a potential loss of the current partner, relationship, resources, status, and extra-pair allies linked to the relationship, such as friends and family of the partner. From the distal perspective, jealousy helps to secure a valued reproductive partner and maintain the pair bond, which, in turn, increases the chances for survival of potential offspring because of its necessity of biparental care (Buss 2013).

Interestingly, in some polygynous societies, women report high jealousy when a new wife arrives, while in others, where the social status

of the women is guaranteed, the older wives report lower jealousy and actively leave sexual activities between the husband and the new wife (Madhavan 2002). Thus, jealousy can be evoked in particularly when connected with loss of status. Accordingly, instead of preserving the relationship, in particularly, women tried to preserve their self-esteem when dealing with jealousy (Bryson 1991). Losing one's status and reputation in an intrasexual competition or mate poaching context might have had serious consequences in the ancestral lifestyle. In general, intrasexual conflict and jealousy seem to be much higher than cooperation among co-wives and co-husbands in polygamous marriages (Jankowiak et al. 2005; Starkweather and Hames 2012), and thus romantic jealousy constitutes an integral strategy of intrasexual competition.

Although the loss of a romantic partner to a rival seems to be similarly significant for both partners, there are some systematic differences between men and women in jealousy. Women, on average, report more intense overall jealousy response than men (Buunk 1997), women more than men are prone to emotional and cognitive reactions when expressing jealousy (Güçlü et al. 2017), and women more than men are upset by an emotional involvement compared to sexual involvement of the partner with a third person (for meta-analyses, see Sagarin et al. 2012; Tagler and Jeffers 2013). These results can be a part of a more general pattern, such as, higher emotional processing among women than in men (Barrett et al. 1998).

Sex Difference in Emotional Versus Sexual Jealousy

The relative sexual versus emotional jealousy is systematically higher among heterosexual men than among heterosexual women, with no significant effect of socioeconomic status, length of relationship, age, history of infidelity gender-role beliefs, interpersonal trust, attachment style, sociosexuality, and culture of honor beliefs on this sex difference (Brase 2014; Frederick and Fales 2016). Importantly, the sex difference in sexual versus emotional jealousy is specific to

heterosexual individuals. More specifically, heterosexual men are more frequently upset about sexual infidelity scenario versus the emotional infidelity scenario than heterosexual women and both homosexual men and women (Frederick and Fales 2016).

Sex differences in jealousy were supported by fMRI studies showing sex difference in jealousy-related brain activation (Takahashi et al. 2006). Furthermore, men recall more cues to sexual infidelity, while women recall rather cues to emotional infidelity (Schützwohl and Koch 2004). Finally, although there are no sex differences in physiological arousal to sexual versus emotional infidelity cues, men show greater startle response to sexual scenarios than women (Baschnagel and Edlund 2016). Thus, sex differences in emotional versus sexual jealousy are not a by-product of self-reports.

Although cross-cultural studies are still rather scarce, the evidence suggests that these sex differences are culturally universal, appearing in populations as different as Canada, the United States, Norway, the Netherlands, Romania, Brazil, Chile, Australia, China, Japan, or Korea (see Buss 2013; Buss and Haselton 2005). However, the magnitude of the sex differences can vary. For example, among the Himba of Namibia, a small-scale natural fertility population, sexual jealousy is much higher than emotional jealousy in both sexes, although the relative sex difference remains (Scelza 2014). Further, a study employing a cross-cultural sample of Hawaiian students reported higher sex differences specifically in emotional jealousy, while sexual jealousy was more influenced by the individualist or collectivist culture of the participants than by sex (Zandbergen and Brown 2015). Moreover, in a majority of studied traditional non-WEIRD populations, higher sexual than emotional jealousy was more frequent than in Western populations (Scelza et al. 2019).

Jealousy as an Evolved Sex-Specific Mechanism

Supposedly, selective pressures acting upon male and female reproductive strategies during the

human evolution are part of the broader picture of the observed sex differences in jealousy. In particular, internal fertilization among mammals leads to paternity uncertainty, which makes the males concerned relatively more with sexual than emotional infidelity of their female partner. For male, female sexual infidelity poses the risk of loose valuable resources by investing into non-biological offspring, which is not the case for females. However, female emotional infidelity poses the risk of losing direct female investments into offspring if leaving with a new male without the offspring or maltreatment or infanticide by another male if leaving with a new male with the offspring. Females are supposed to be concerned with survival of their offspring even more than males, because female minimal necessary biological investment into reproduction is relatively higher and riskier. In species with prematurely born infants, like humans, biparental care is essential for their survival, in particularly during the first years of life. Losing paternal long-term protection and investments because of emotional involvement with another female would thus be more costly for the female and the child/children. Women thus feel more threatened by emotional involvement of their partner, because they are at risk of losing direct investments, such as resources, protection, and/or paternal care (Buss et al. 1992; Daly and Wilson 1988). In general, this logic would predict higher emotional than sexual jealousy in both men and women (e.g., Buunk et al. 1996) but also a relatively higher sexual versus emotional jealousy in men than in women. As outlined above, this has been supported by some research (Sagarin et al. 2012; Tagler and Jeffers 2013).

Moreover, men more than women are sensitive to loss of paternity opportunities than to paternity uncertainty (Edlund et al. 2019). Thus, when losing an opportunity to reproduction with a valued potential or real partner, men become more distressed than women. Accordingly, jealousy is being evoked particularly when the partner is perceived as of a high mate value (Güçlü et al. 2017), and also rivals of high mate value evoke relatively more jealousy (Dijkstra and Buunk 2002). Thus, involvement with a third party

implies not only the risk of paternity uncertainty, loss of the resources, allies, relationship, status, and self-esteem, but also, in particularly for men, loss of the reproductive opportunities.

Further, if the evolutionary rationale is true, then we might expect similar sex differences in jealousy among other nonhuman primates with monogamous bonds and dependent prematurely born offspring. There is some evidence that behaviors similar to jealousy and mate guarding exist in monogamous primates, such as *callicebus* (Cubiciotti and Mason 1978). Among these primates, situations evoking jealousy when placing a female near another male increases testosterone and cortisol in males which is connected to stress and aggressiveness, respectively, and activates the cingulate cortex which is associated to social exclusion (Maninger et al. 2017). Differences specifically in sexual versus emotional jealousy are yet to be tested. We would expect higher jealousy in less promiscuous species and higher sexual jealousy in males in species with relatively smaller testicles which does not favor sperm competition, such as in gorillas.

Conclusion

In general, sex differences in jealousy are one of the frequent critiques of the evolutionarily based research on human psychology and behavior. Sex differences in emotional versus sexual jealousy can be influenced by methodological specificities of the studies. For example, student sampling leads to larger sex differences in jealousy than nonstudent or random sampling (Sagarin et al. 2012). Further, forced-choice measures of emotional versus sexual jealousy may lead to different results although it rather seems that both report result in the same direction (Bendixen et al. 2015). Although there are some methodological discrepancies between specific studies, leading to divergent results, the sex difference in emotional versus sexual jealousy seems to be robust and universal (Sagarin et al. 2012). Importantly, the sex differences in jealousy do not represent categorical differences but rather dimensional differences which reflect differences in magnitude between

the two groups with a significant overlap between them.

The focus on differences between men and women should not overshadow other individual differences in jealousy that might be important for the evolutionary and other interdisciplinary theories. Other factors might predict jealousy more strongly than sex, such as population, sexual orientation, type of relationship, life history strategy, self-esteem, attachment, and others (Martínez et al. 2017). Mapping the proximate and ultimate mechanisms underpinning jealousy should be the focus of future studies.

Sex Differences in Long-Term Mating Preferences

David P. Schmitt¹ and David M. Buss²

According to Sexual Strategies Theory (Buss and Schmitt 1993), our species comes equipped with specialized mate preference adaptations. Some

mate preference adaptations are designed for *long-term mating*, and many of those are designed to motivate men and women to pursue long-term mateships differ in different ways.

Women's Specialized Long-Term Mating Psychology

Evolutionary psychologists have hypothesized women possess long-term mate preferences for cues to a man's *ability* and *willingness* to devote resources to her and their offspring (Buss 1989; Ellis 1992). Such cues include a man's status and prestige which, depending on culture, may involve hunting ability, physical strength, or other locally relevant attributes, as well as his ambition, work ethic, intelligence, social dominance, and age. Several lines of evidence support the hypotheses about women's long-term mate preference adaptations, including self-reported mate preference surveys, reactions to experimental manipulations, ethnographic evidence from pre-industrial cultures, examinations of marital mate choice, and evidence from men's courtship effectiveness and associated fertility outcomes.

Using self-report surveys, Buss and Barnes (1986) were among the first to test whether women (more than men) prefer cues related to a man's ability and willingness to devote resources. They documented women more strongly prefer long-term mates who have a good earning capacity ($d = -0.82$), are a college graduate ($d = -0.60$), and possess intelligence ($d = -0.19$). In 1992, Feingold (1992) meta-analytically reviewed the extant literature (including 32 independent samples) on self-reported mate preferences and found sex differences were prevalent across college students and community samples with women more greatly desiring socioeconomic status ($d = -0.69$), ambition ($d = -0.67$), and intelligence ($d = -0.30$) in potential long-term mates. Numerous additional investigations have since replicated these basic sex differences in long-term mate preferences among college students (Buss and Schmitt 1993; Buunk et al. 2002; Kenrick et al. 1993; Regan 1998; Regan and Berscheid 1997).

In 1994, Sprecher examined mate preferences across a nationally representative sample of the United States and found women, more than men, valued a long-term mate who had a steady job ($d = -0.73$), earned more than they did ($d = -0.49$), was highly educated ($d = -0.43$), and was older by 5 years ($d = -0.67$). In a 2001 cross-generational analysis of identical mate preference questionnaires administered to Americans from 1939 to 1996, both men and women increased valuing the attribute good financial prospects and decreased valuing ambition/industriousness, though the degree of sex differences in these items largely persisted in strength across more than 50 years (Buss et al. 2001).

Cross-culturally, Buss (1989) found across 37 cultures that women, more than men, universally desired a slightly older long-term mate. Buss also documented sex differences in preferences for good financial prospects were nearly universal (97%), and sex differences in preferences ambition/industriousness were prevalent (78%). Others have replicated these cross-cultural findings, documenting sex differences in resource-related mate preferences for good financial prospects, social status, ambition, and slightly or somewhat older age as *pancultural* universals across 100% of more than 50 studied nations (Lippa 2007; Zentner and Mitura 2012).

An additional source of evidence regarding women's hypothesized preferential emphasis on men's ability and willingness to devote resources comes from studies involving reactions to randomly assigned scenarios or actual real-life interactions with randomly assigned experimental confederates. Townsend and Levy (1990) exposed samples of women (undergraduates and law students) to photographic slides of men and had the women rate how likely they would be to date, engage in short-term mating, or engage in long-term relationships with the men. Men's physical ornamentation in the slides was experimentally manipulated to provide cues to high status (i.e., men wore a blazer and Rolex watch), moderate status (i.e., white t-shirt), or low status (i.e., Burger King outfit). The photographs further contained either a physically attractive man or a homely man. Across samples, Townsend and

Levy repeatedly found women preferred to mate with homely/high-status men much more than handsome/medium-or-low-status men, and these effects were most pronounced when women considered the men as *long-term* mates.

Sadalla et al. (1987) had participants view videos of experimental confederates (either men or women) engaging in same-sex encounters within which they were randomly assigned to act as either high in dominance (i.e., upright posture, shoulders straight, move with ease and confidence) or low in dominance (i.e., smiled a lot to appease others, averted their eyes a lot, avoid invading personal space). Women who viewed the videos found high dominance men much more attractive than low dominance men, whereas men did not find high dominance women attractive (see also Ahmetoglu and Swami 2012).

In a real-world test of women's mate preferences for status, Guéguen and Lamy (2012) conducted a naturalistic experiment to evaluate whether women's reactions to a request for their phone number were affected by men's apparent status (in this case, driving different types of cars). Women approached by a man driving an expensive Audi A5 Ambition Luxury gave their number to the man 23% of the time. Women approached by a man driving a mid-priced Renault Mégane gave their number 13% of the time. Women approached by a man driving a 15-year-old Renault 5 Super Campus (worth only a few hundred dollars) gave their number 8% of the time. Women's preferences for resource-related cues appear to affect their real-world mating behavior.

Another test of women's long-term mate preferences for men's ability and willingness to provide resources comes from examining whether the preferences disappear or become sharply attenuated when women have ample resources of their own, as predicted by the structural powerless hypothesis (Buss and Barnes 1986) and traditional social role theory (Eagly and Wood 1999). It could be women prefer cues to men's ability and willingness to provide resources, but only because women are structurally denied access to resources in a particular culture (Buss 1989). Addressing this alternative explanation, Townsend (1989) found women in medical school are *more*

selective of a future mate's financial status, not less. Regan (1998) found as women's mate value goes up, so does their insistence on men's high status and resources (i.e., they "want it all"; see also Buss and Shackelford 2008). Having higher status and resource-related traits appears not to attenuate women's mate preferences for men's ability and willingness to provide resources.

Most studies of real-world *marital* choice find women, but not men, tend to marry partners higher than average in terms of status and resource-related traits (men with well-below average status and resources are more often shut out of the mating market altogether); and women, but not men, tend to marry partners who are older – a potential cue to his accrued status and resource levels (Kenrick and Keefe 1992; Perusse 1994; Trivers 1985). Lichter et al. (1995) found this effect was particularly conspicuous when men are especially plentiful (due to male-biased sex ratios). Thus, women's long-term mate preferences do appear to drive their actual choices in the context of marriage.

In pre-industrial cultures, men's status and hunting ability, and where applicable wealth, are often linked to increased fertility (Betzig 1986; Hurtado and Hill 1992; Smith 2004). Wealth is also linked to increased fertility among men, but not women, in modern cultures (Cashdan 1996; Mealey 1985; Nettle and Pollet 2008). Height, a cue to physical health and interpersonal dominance, is a key factor in both women's long-term mate choice and men's long-term courtship and fertility success (Fink et al. 2007; Nettle 2002; Stulp et al. 2013). Pawlowski et al. (2000) found childless men were 1.25 inches shorter than men with children, and women rate 5'11" as ideal height for partner, but 80% of men's personal ads list their height as 6' or more (Kenrick et al. 1990). Other masculine traits preferred by women have also been linked to increased fertility in men (e.g., deeper voice; Apicella et al. 2007). Some evolutionary psychologists view men's status and dominance contests as more about intimidating other men than about fulfilling women's desires (Puts 2010). Men's long-term mating psychology matters, as well, when it comes to courtship and fertility.

Men's Specialized Long-Term Mating Psychology

According to Sexual Strategies Theory (Buss and Schmitt 1993), men have evolved preferences for cues to youth, health, and genetic quality as these provide signals of a woman's fertility status (i.e., odds of conceiving *currently*) and potential reproductive value (i.e., number of children a woman could have *into the future*). Consequently, men are expected to desire physical features indicative of a woman's relatively youthful age (e.g., neonous face, full lips, clear and glowing skin, clear and wide eyes, small chin, lustrous and long hair, good muscle tone; Sugiyama 2005), to desire physical features indicative of high-fertility estrogen levels (e.g., high femininity in face, voice, finger lengths, and a 0.7 waist-to-hip ratio of body fat distribution), and to desire physical features indicative low genetic mutation load (e.g., facial and bodily symmetry). Additionally, men should preferentially desire attributes that indicate a woman would not be unfaithful in a long-term partnership (deleteriously affecting paternity certainty), has good parenting skills, and would have a compatible personality (Buss and Schmitt 1993).

One source of evidence for evaluating these hypothesized preferences comes from self-report surveys that ask men and women to rate, rank, or nominate what they prefer in long-term mates. In 1986, Buss and Barnes found men ranked physical attractiveness as more important in long-term mating than women do ($d = 0.92$). Feingold (1990) conducted a meta-analysis of self-reported mate preferences surveys and confirmed men prefer physical attractiveness in potential long-term mates more than women do (overall $d = 0.54$). Numerous studies since have replicated these basic sex differences in long-term mate preference for physical attractiveness (Buss and Schmitt 1993; Buunk et al. 2002; Kenrick et al. 1993; Regan and Berscheid 1997). Buss (1989) surveyed long-term mate preferences *across 37 cultures* and found men prefer younger women as long-term mates in 100% of cultures, and men preferred "good looks" in potential long-term mates more than women did across 34 of 37 cultures (92%). In no cultures did women prefer

physical attractiveness significantly more than men did in long-term mates.

In explaining cross-cultural variation in the size of sex differences in preferences for physical attractiveness, Gangestad et al. (2006) showed women's and men's mate preferences for good looks are closely linked to local pathogen levels, with good looks being more important in high pathogen cultures, even after controlling for income, geographical region, and latitude (see also, Little et al. 2007). Lippa (2007) found sex differences in long-term mate preferences for good looks were a *pancultural universal*, evidenced in 100% of 53 nations, with an average effect size of $d = 0.55$. Zentner and Mitura (2012) found sex differences in long-term mate preferences for good looks were a *pancultural universal* across 100% of 10 nations, and counter-intuitively sex differences were *larger* as sociopolitical gender equality increased across nations, with low sociopolitical gender equality nations displaying smaller sex differences ($d = 0.24$) compared to medium ($d = 0.43$) or high sociopolitical gender equality nations ($d = 0.51$). This last finding suggests increased sociopolitical gender equality in a nation does not reduce the size of sex differences in mate preferences. If anything, sociopolitical gender equality increases psychological sex differences (Schmitt 2015).

Sprecher et al. (1994) examined long-term mate preferences in representative sample of the USA and found men, more than women, especially value good looks ($d = 0.65$) and younger age ($d = 0.99$). In a review of mate preferences changes in the USA across 57 years, Buss et al. (2001) found both men and women have increased the relative importance they place in physical attractiveness in long-term mates. However, men's increased ranking of good looks (from 14th place in 1939 to 8th place in 1996) was greater than women's increased ranking (from 17th place in 1939 to 13th place in 1996). It seems the relative emphasis that men, relative to women, place on physical attractiveness has at least persisted, if not grown, across American generations.

Many hypothesized sex differences in mate preferences persist across developmental age, as

well. As men and women get older, sex differences in age preferences become *more* intense. Kenrick and Keefe (1992) found men at age 25 prefer to marry a woman who is about four years younger, with minimum acceptable age of 20 and a maximum age of 30. Women at age 25 would marry a man who is between 25 and 35, ideally about 4 years older. At age 65, however, men would marry a woman between the ages of 50 and 60 (ideally about 10 years younger), whereas at 65 women still want an older man, between 65 and 75 years old. Similarly, Schwarz and Hassebrauck (2012) surveyed 21,245 single people between 18 and 65 (average age = 31) and found men valued physical attractiveness and relative youth more than women, regardless of age or education level. There is one revealing caveat to the youthful desires of men, however. Kenrick et al. (1996) documented that teenage men prefer a mate who is a little older, which was explained as men's preferences being sculpted to desire the highest fertility women (women in their 20s). It is not the case that men simply want someone similar, or perhaps a little younger. Men's long-term preferences for age are anchored by the actual peak fertility levels of women. Finally, studies that have examined long-term versus short-term mate preferences have documented that men's heightened preferences for physical attractiveness and youth are specific to long-term mating.

An additional source of evidence regarding men's hypothesized emphasis on fertility-related cues such as youth and physical attractiveness in long-term mates comes from studies involving personal responses to randomly assigned scenarios or actual real-life interactions with randomly assigned experimental confederates. Meta-analyses of experimental interactions show men react more positively than women do when they personally interact with a highly attractive opposite-sex partner (effect size in men $d = 1.23$; effect size in women half as large, $d = 0.61$; Feingold 1990). Cues related to relative youth and high fertility also show evidence of special design in men's mate preferences. Schaefer et al. (2006) showed men exposed to targets with feminine faces or voices react to those women with greater feelings of attraction.

Johnston and Franklin (1993) had male participants morph female faces until they achieved an “ideal” face. The final female face had geometric proportions indicative of a 14-year-old girl. Many of these cues to youth and fertility are universally valued by men across cultures and time periods (Cunningham et al. 1995; Jones 1995; Langlois et al. 2000). Men across most cultures, for example, prefer feminized faces and body shapes indicative of high estrogen (Perrett et al. 1998; Singh and Young 1995). Men across most cultures prefer waist-to-hip ratios in women that are linked with adaptive estrogen levels and higher fertility (Singh 1993), a preference finding documented even among blind men feeling mannequins (Karremans et al. 2010). It appears many of these specific cues to youth and fertility activate domain-specific areas of men’s brains (Thornhill and Gangestad 1999), especially in the nucleus accumbens (Platek and Singh 2012). One caveat to this is that in cultures with frequent warfare the need for more masculine sons may attenuate the preference for a feminine waist-to-hip ratio (Cashdan 2008). Moreover, cultural variations in disease prevalence, paternal investment, and visual experiences can predictably moderate mate preferences for adaptive physical attributes (see Pisanski and Feinberg 2013).

Behaviorally, when men are experimentally exposed to physically attractive women they react by being more likely to value money, experience greater ambition, are more creative, and are willing to take more risks (Ronay and von Hippel 2010). Conversely, just holding \$2000 in one’s hands elicits in men, but not women, stronger desires to mate with a physically attractive partner (Yong and Li 2012). Men told they were making phone call to a woman lowered their voice (a feature women typically find attractive; Puts 2005), but only if the woman was portrayed in a picture as highly physically attractive (Hughes et al. 2010). Men also give bigger tips to women if they are physically attractive, younger, have larger breasts, and smaller body size (Lynn 2009), buy bigger engagement rings for younger women than older women (Cronk and Dunham 2007), and are more likely pay for dinner

if their date is physically attractive (with no such effects seen in women; Stirrat et al. 2011).

If men’s preference for physical attractiveness in long-term mates is a psychological adaptation, physically attractive women should tend to have more children (assuming no modern confounds such as contraception use). In a study of 88 postmenopausal Austrian women from a rural community, among those who did not use contraception in their lifetime, higher objective symmetry, facial femininity, and overall physical attractiveness were linked to having more children (Pflüger et al. 2012). Women who have lower testosterone (Barrett et al. 2012) and higher estrogen (Law Smith et al. 2012) tend to be more feminine and have fertility-linked traits such as wanting more children. Women who, in their grade school photos, are judged more physically attractive have higher lifetime fertility (attractive women had 11% more children than those who were unattractive; Jokela et al. 2010) and are more likely to be married (Harper 2000). Hill and Hurtado (1996) found physically attractive women among the foraging Ache foragers also have higher lifetime fertility. In a study of women who do not use contraception, physically attractive women were found to have more children (Pflüger et al. 2012). These results provide supportive evidentiary breadth for viewing men’s preferences for long-term mates who are physically attractive as evolved psychological adaptations.

Perhaps the strongest test of the existence of long-term mate preference adaptations comes from analyzing actual marriages, especially who marries whom and how reproductively valuable those choices are over the long run. Most studies have found that men, more than women, tend to marry younger partners who are closer to peak fertility (Kenrick and Keefe 1992; Perusse 1994). As men age, this mate preference mechanism results in newly married men marrying younger and younger women (Kenrick et al. 1990). In the United States, the average man’s first marriage is to a woman who is 3 years younger, the average man’s second marriage is to a woman who is 5 years younger, and the average man’s third marriage is to a woman who is 8 years

younger (Guttentag and Secord 1983). In a study of the wealthiest 400 people in the United States, wealthy men tend to be married to someone 7 years younger, and among second marriages wealthy men are married to someone 22 years younger, on average (Pollet et al. 2013). Wealthy women's spouses, in contrast, did not differ in age from the general population of the United States. In Sweden, a retrospective look at marriages in the 1800s found the average man's second marriage was to a woman 11 years younger (Guttentag and Secord 1983). Also in Sweden, men who marry first wives who are 6 years younger have the highest levels of lifetime fertility (Fieder and Huber 2007). Long-term mate preferences for youth appear to pay men actual dividends in the currency of reproductive success.

As noted earlier, men who have higher social status tend to emphasize physical attractiveness more in potential long-term mates. Researchers have found men with more masculine or male-typical psychologies tend to prefer feminized female faces (Smith et al. 2010), as do men who consider themselves more attractive to the opposite sex (Burris et al. 2011; Kandrik and DeBruine 2013), and those who have high testosterone (Welling et al. 2008). When men can afford to, they insist on physically attractive mates. Gay men and heterosexual men show very similar long-term mate preferences with physical attractiveness being critical to both (Bailey et al. 1994), suggesting that mate preference adaptations for physical attractiveness are specific to the psychology of the desirer (men), not the biological sex of the target of desire (whether men or women).

Conclusion

Several lines of evidence confirm the existence of women's and men's long-term mate preference adaptations, including self-reported mate preference surveys, reactions to experimental manipulations, historical records, ethnographic evidence from pre-industrial cultures, examinations of actual mate choice, and evidence from courtship effectiveness and associated fertility outcomes.

Sex Differences in Morbid Jealousy

Kristin Cianciolo and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Synonyms

Conjugal paranoia; Delusional jealousy; Othello jealousy; Pathological jealousy

Jealousy is an affective response to a real or perceived threat to a valued relationship by a rival, as is seen in sexual, romantic, familial, and platonic relationships. Jealousy may be functional because it elicits a response that aims to restore that relationship. For example, sexual jealousy motivates the individual to secure exclusive sexual access to one's partner (see "Jealousy" entry).

Though levels of romantic jealousy are approximately equal between men and women, men tend to react more negatively to sexual infidelity, whereas women tend to react more negatively to emotional infidelity (Bendixen et al. 2015; Easton et al. 2007; Sagarin 2005; Schützwohl 2004). Theoretically, sexual infidelity is more costly for men because it increases the risk of cuckoldry, loss of partner, and enhances the reproductive success of rivals, whereas emotional infidelity is more costly for women because it may indicate that a partner is redirecting time and resources to a rival.

There are times when romantic jealousy is hypersensitive and no longer functional. One such example is *morbid jealousy* (also referred to as *pathological jealousy*, *delusional jealousy*, *Othello syndrome*, and *conjugal paranoia*; Easton et al. 2007). A morbidly jealous individual experiences persistent, extreme, and irrational beliefs

surrounding their partner's sexual and/or emotional infidelity without any logical evidence (Kingham and Gordon 2004). Symptoms may include delusions, accusations, stalking, threatening, or spying, which may result in domestic violence, suicide, or homicide (Soyka and Schmidt 2011; Mullins 2010; Seeman 2016). These behaviors are costly because they use time and resources to combat a nonexistent or exaggerated threat (Kingham and Gordon 2004) and can be quite costly as it sometimes results in suicide or homicide.

Morbid jealousy may be a disorder of sexual and emotional jealousy mechanisms. Easton, Shipper, and Shackelford (Easton et al. 2007) tested this hypothesis by reviewing case histories from individuals diagnosed with morbid jealousy. Specifically, they found that among those with morbid jealousy, more men than women showed signs of sexual jealousy, whereas more women than men showed signs of emotional jealousy. Also similar to non-clinical samples, men's description of rivals, more so than women's, focused on their status and resources, whereas women's description of rivals, more so than men's, focused on youth or physical attractiveness. These data are consistent with the notion that morbid jealousy is a disordered manifestation of evolved jealousy mechanisms.

Conclusion

Men and women show differences in the symptoms of morbid jealousy.

Sex Differences in Navigation

Joshua New¹ and Danielle Truxaw²

¹Barnard College, Columbia University,
New York, NY, USA

²Harvard University, Cambridge, MA, USA

Synonyms

Division of labor; Navigational strategies; Reproductive roles; Sexual dimorphism; Spatial abilities

Definition

Some of the few reliable differences between women's and men's cognitive abilities are in the domain of spatial cognition. While reflecting a number of social, cultural, and experiential

factors, these cognitive sex differences have also been attributed in evolutionary accounts to a number of ultimate causes. In these accounts, men and women were inhered with some differentiated spatial abilities and predispositions over evolutionary time – distinctions which reflected the specific adaptive problems that confronted women and men in their respective reproductive roles and primary foraging labors.

Introduction

The necessity of navigating the environment has undoubtedly constituted a powerful selective force on the cognitive abilities of humans for encoding, representing, remembering, and using spatial information (Silverman and Eals 1992). Any individual who leaves their home is at risk of becoming lost and separated from their group – which in ancestral environments and hunter-gatherer societies would present many potential dangers including exposure to the elements, predators, hostile people, and other physical hazards. Males and females develop and survive in the same physical world – and should correspondingly have largely similar cognitive mechanisms for navigating (Shepard 1994). However, natural and sexual selection may, in some cases, have impacted men and women differently and brought about distinctions in their spatial abilities through modification, elaboration, or enhancement (Geary 1995).

There is long-standing evidence and general acknowledgment that some of the most reliable sex differences are in the domain of spatial perception and representation. These sex differences for mental rotation (Silverman et al. 2007), object location memory (Silverman and Eals 1992), and wayfinding (Malinowski and Gillespie 2001) have been central to many theories – and debates about – the origins of such sex differences. Although these differences have been variously ascribed to proximate causes of a biological (e.g., neurological structures and hormones) and socio-cultural nature (e.g., experience and stereotypes), a number of evolutionary accounts have been advanced which vary

considerably in their explanatory scope, weight of empirical support, and emphasis on either reproductive roles and strategies or on foraging activities as their ultimate causes.

Spatial Cognition in Women and Men

Many decades of research have led to the consensus that spatial abilities are among the few domains of cognition that reliably differ between men and women – seminally documented as only one of four domains to be considered well-established by Maccoby and Jacklin (1974) and later confirmed in a number of meta-analyses (e.g., Voyer et al. 1995). The effect sizes of these differences do depend greatly, however, on the particular type of spatial ability being considered. Although many tasks reveal no, or only small sex differences, there are large and reliable sex differences in which men outperform females in tests of spatial perception – identifying spatial relations among distracting information, and spatial visualization – the mental transformation of spatial information in multiple stages. However, it is the third ability identified in these influential meta-analyses, mental rotation, that exhibits the largest and most reliable male advantage. Men’s greater abilities for imagining and transforming mental representations of two- and three-dimensional objects have been extensively and cross-culturally replicated (Silverman et al. 2007). These well-founded male advantages for mental rotation and other spatial abilities, along with the later discovery of women’s superiority at remembering object locations (Silverman and Eals 1992), have been focal points in the debate about whether men and women do have any inherent cognitive differences – unlike their similarities in so many other cognitive abilities (Hyde 2005).

Such sex differences in spatial abilities were, early on, largely considered from influential perspectives as the consequences of socialization and learning, as well as gender identity, roles, and stereotypes (see Eagly and Wood 2013 for review). Empirical evidence has steadily accrued that these socio-cultural factors

can moderate – if not necessarily cause – such sex differences. Despite the general acknowledgment that spatial abilities are the results of socio-cultural factors interacting with innate abilities and predispositions (cf. Eagly and Wood 2013), these proximal factors have been investigated largely in parallel with the more distal accounts advanced from an evolutionary perspective. A number of evolutionary hypotheses have been proposed, starting with those arising out of comparative studies of spatial cognition (i.e., mating systems), and later from those domains increasingly unique to human beings (e.g., the sexual division of foraging labor). These adaptationist theories, though distinct, are largely divisible into two groups according to their emphasis on the underlying selective pressures – whether focusing on the differences in women and men’s reproductive roles and strategies or their primary activities for obtaining nutritional resources.

Home Ranges

Sexual selection is more likely than natural selection to bring about phenotypic differences between the males and females of a species (Trivers 1972). Unsurprisingly, the first – and most of the adaptationist accounts to follow – concerned how differences between females’ and males’ reproductive roles and strategies could have brought about such differences in their spatial abilities. A first theory of this kind, though now largely set aside, was based on natal dispersal – wherein the sex which travels further from its birthplace to its breeding site should be proportionally more proficient at navigating (Silverman and Eals 1992). However, in humans, juvenile dispersals are larger by females (Koenig 1989), whereas males perform better at the relevant spatial tasks (e.g., wayfinding; Moffat et al. 1998; Silverman et al. 2000). Likely, the more relevant metric of overall mobility to sex differences in humans is that of home range size – the area in which an individual lives and customarily navigates throughout while pursuing resources, seeking mating opportunities, and caring for

offspring. Differences in home range sizes between the males and females of a species commonly reflect their mating system (Gaulin and FitzGerald 1986) – notably in polygamous species in which the males travel more extensively in their competitive efforts to mate with multiple females. Gaulin and FitzGerald reasoned that the larger home range of males in such species – and the greater information-processing requirements in reaching potential mates – would bring about a corresponding enhancement in their spatial abilities (1986). This relationship between spatial abilities and range size as a function of mating system was supported in their oft-cited series of studies comparing monogamous and polygamous species of voles. Males of the polygamous species had larger home ranges, spatial abilities superior to females of the species, and larger neural structures implicated in spatial navigation. By comparison, males of the monogamous vole species did not differ significantly from the species' females with respect to home range size, spatial abilities, or their associated neural structures (Jacobs et al. 1990).

Human males do exhibit an early-appearing and persistently larger home range than females (Ecuyer-Dab and Robert 2004). Several avenues of anthropological and comparative research suggest that humans are a mildly polygynous primate species (Alexander et al. 1979; Low 1988) and have been for most of their history – a characterization that population genetic research is increasingly supportive of (e.g., Dupanloup et al. 2003). Studies of the Tse and Tjimba of Namibia, for instance, illustrate this scenario – males travel more extensively than women, and those men travelling further father children with more women (Vashro and Cashdan 2015). This first systematic account of sex differences in spatial abilities does, therefore, readily anticipate a male advantage in human spatial abilities, as it does for analogous effects in other animal species. However, the core relationship of this mating-competition hypothesis between range size and spatial abilities is equally central to other accounts but which attribute the differences in range size to other domains of selective pressures such as foraging activities and warfare.

Reproductive Roles

Another account concerning the reproductive domain, the fertility and parental care hypothesis, proposes that such range size differences result, at least in part, from selection pressures on females to reduce their spatial abilities during particular reproductive periods (Sherry and Hampson 1997). The greater dependence of offspring on the continued survival and parental efforts of the mother (Campbell 1999) may have acted selectively on females to more closely circumscribe their travel and exposure to dangers (Sherry and Hampson 1997). Females far less frequently involve themselves in aggressive situations (Wilson and Daly 1985), primarily pursue gathering (Marlowe 2007) and – if any – lower-risk hunting strategies (e.g., trapping and netting; see Ecuyer-Dab and Robert 2004 for discussion), and are less inclined towards long-range navigating – an energetically costly and hazardous activity in natural environments (Ecuyer-Dab and Robert 2004). This hypothesis also accounts uniquely well for a number of related characteristics such as females' greater anxiety (Lawton 1994) and lower confidence in navigation (Picucci et al. 2011) and a systemic relationship between spatial cognition and the fluctuation of female sexual hormones (Hampson 1990).

Considerable evidence supports the organizational and activational effects of sex hormones on spatial abilities (see Liben et al. 2002 for review). The fertility and parental care hypothesis provides a structured adaptationist rationale for their effects in sexually mature adults, beyond that of conventional perspectives in which sex hormones are seen as proximal, yet sufficient causes in themselves of such differences (cf. Miller and Halpern 2014). The fertility and parental care hypothesis finds these proximal mechanisms on more distal causes – that women's spatial abilities and mobility are decreased in rough correspondence with periods of potentially elevated reproductive and childrearing demands (Sherry and Hampson 1997). In line with such reasoning, women's lowest performance in spatial tasks is observed during the periods of highest estrogen levels in their cycle (e.g., Hampson 1990) and during pregnancy

(Woodfield 1984). Conversely, women's best performance in some spatial tasks is observed during the low-estrogen phase of the monthly cycle when they perform comparably to males (e.g., Chabanne et al. 2004). It has also been strongly advanced that humans' sexual dimorphic spatial abilities might reflect compounded selection pressures acting to both increase men's spatial abilities while conversely curbing women's spatial abilities and mobility during particularly important reproductive periods (Ecuyer-Dab and Robert 2004).

One other account of sex differences in spatial abilities – more complexly related to reproductive strategies – concerns the far greater involvement of males in hunter-gatherer societies in small-scale warfare (Daly and Wilson 1988). In one of the earliest proposals relating intrasexual competition to spatial abilities in humans, Geary (1995) advanced that long-range expeditions to ambush and raid other groups of people carried out mostly, if not entirely, by men would have selected for their greater large-scale navigational abilities. In hunter-gatherer societies, such high-risk forays figure prominently in male mortality and individual differences in male reproductive success. By this account, mental rotation and a number of other dynamic spatial abilities that show a male advantage – such as estimating velocities, and intercepting and throwing objects – may have arisen for other purposes, notably physical competition and warfare (see Ecuyer-Dab and Robert 2004 for review).

Sexual Division of Labor

An entirely different domain of selection pressures has been emphasized in a prominent evolutionary account – one concerning how women and men have primarily obtained nutritional resources and the division of foraging labors between hunting by men and gathering by women. In the overarching sexual division of labor hypothesis, women are purported to have been largely engaged in gathering sessile plant resources and catching small game within smaller ranges whereas men predominantly hunted for larger

game animals over greater ranges (Silverman and Eals 1992). Although the hypotheses concerning reproductive goals and strategies have principally addressed men's greater performance in tests of spatial abilities, the closer consideration of spatial skills necessary for successfully gathering and for hunting have provided finer-grained expectations about men's and women's relative strengths and weaknesses in spatial cognition. Rather than presuming that one sex possesses roundly superior spatial abilities, the predominant engagement of women in gathering and of men at hunting may have separately enhanced, modified, or elaborated each spatial ability in proportion to their usefulness for foraging activities – enhancing those spatial abilities that would have proven especially useful to women in their gathering activities and to men in their hunting activities (Silverman and Eals 1992).

In their sexual division of labor hypothesis – also termed the hunter-gatherer hypothesis for its emphasis on foraging labors – Silverman and Eals advanced that humans' sexual dimorphism in spatial abilities reflected the primary engagement of women in gathering and of men in hunting over evolutionary time (1992). The sexual division of labor hypothesis is one of the most extensively articulated – and empirically tested – evolutionary accounts of spatial sex differences. It is a long-held and extensively supported feature of hunter-gatherer societies that men have predominantly hunted and women primarily gathered (e.g., Marlowe 2007) – although this sexual division of labor may have emerged more recently in human evolutionary history than commonly presumed (e.g., Kuhn and Stiner 2006). Whenever this division emerged, many of the greater abilities that males exhibit in spatial tasks would have undoubtedly proven advantageous to males in their hunting of large, mobile game over large distances and over unpredictable routes. As Silverman and Eals originally cite – and which have been more thoroughly evidenced since – males are especially capable at mentally rotating objects (e.g., Voyer et al. 1995), reading maps (e.g., Malinowski 2001), and learning mazes (e.g., Moffat et al. 1998). Of these spatial abilities, the male advantage is largest and most reliable for

mental rotation – an ability for representing and transforming spatial information which has been related to navigation skills (Hegarty et al. 2006; Malinowski 2001; Moffat et al. 1998) and is likely subserved by some of the same neurological mechanisms (see Saucier et al. 2002 for discussion). In tests of wayfinding, individuals identify their position and then navigate to an unseen target location – a critical spatial competence for successfully hunting and efficiently transporting game directly home. Men have been found in the majority of studies to perform better in general wayfinding tasks (Coluccia and Louse 2004), whether in virtual (e.g., Moffat et al. 1998; Sandstrom et al. 1998) or real-world environments (Malinowski and Gillespie 2001; Silverman et al. 2000).

The general advantages for males at large-scale wayfinding may also reflect sex-specific tendencies to use navigation strategies that are best suited for larger ranges – in addition to the underlying spatial abilities that differ between men and women. Men typically favor the use of top-down, survey representations of their environment, and navigate with respect to cardinal directions, physical distances, and relatively few landmarks (Lawton 2010). These orientation strategies are positively correlated with successful navigating (Hegarty et al. 2006) and may have proven an optimal approach for traversing larger and less-familiar spaces over new and erratic courses (Ecuyer-Dab and Robert 2004). Men's advantages for wayfinding at the environmental scale may result, in part, from their greater reliance than women on Euclidean strategies and more distal information to navigate. Accordingly, this difference between men and women's abilities for navigation can be sizably reduced, or even eliminated, by testing participants in a smaller, indoor environment where distal, absolute information (i.e., cardinal directions) is unavailable (Sandstrom et al. 1998).

The sexual division of labor hypothesis readily accounts not only for the male advantages in spatial abilities but also for the spatial task in which women are uniquely found to consistently outperform men. First reported by Silverman and

Eals (1992) in support of their hunter-gatherer theory, women were found to have superior memory for the locations of objects in an array. Although the effect size of females' advantage for object location memory is smaller than that of men's advantages for mental rotation, it has been oft-replicated (Choi and Silverman 1996; Dabbs et al. 1998), and demonstrated in adolescents and adults (Voyer et al. 2007), in paper-and-pencil tasks and real-world environments (Silverman and Eals 1992), and in most of the ethnic groups and countries tested thus far (Silverman et al. 2007).

This female advantage for object location memory (OLM) has been largely demonstrated in small-scale spatial tests (e.g., desktop) – a scale at which gatherers were theorized to commonly search for, and periodically revisit, food plants in complex banks of vegetation (Silverman and Eals 1992). However, gathering also requires navigating to, and often between, the locations of potential nutritional resources over far greater distances than OLM appears to function. There is some evidence that females may be advantaged in their survey (geometrical) representations of gathering-relevant locations over greater spatial ranges (New et al. 2007). These demonstrated abilities for precisely encoding and recalling the locations of particular items may have been selectively enhanced in women in support of their primary foraging efforts – notably the periodic return to locations of potential nutritional resources such as fruiting trees and traps set for smaller prey.

Whereas men favor Euclidean approaches that rely less on landmarks, women generally favor non-Euclidean spatial strategies – navigating according to environmental information (i.e., landmarks) along specified routes when available (Dabbs et al. 1998; Lawton 2010). This makes the ability to implicitly encode navigational landmarks particularly useful for women. Accordingly, women possess better knowledge of landmarks than of Euclidean knowledge (Sandstrom et al. 1998), navigate better when using landmark information (Saucier et al. 2002), and provide more landmarks and landmark relationships when giving directions (Choi and

Silverman 1996; Dabbs et al. 1998). Whereas Euclidean strategies may have been optimal for hunting over larger and less familiar ranges, landmark strategies could have proven more useful to gathering activities in smaller and more familiar areas. Destinations with routes specified by orienting and confirming landmarks can not only be followed accurately, efficiently, and reliably – they can themselves be easily and accurately communicated to others.

Conclusion

Navigating the physical environment has constituted a powerful and constant selective force on humans – bringing about considerable cognitive abilities in women and men for learning and using spatial information. These spatial abilities, however, constitute one of the relatively few domains in which males and females demonstrate substantive and reliably different cognitive capacities. Such abilities – and noted sex differences – are undoubtedly attributable in some part to social, cultural, and experiential factors (Coluccia and Louse 2004). However, a number of evolutionary frameworks have advanced that there are also inherent differences between females' and males' capacities and predispositions for spatial knowledge and reasoning. These theories about the sexual dimorphism of human spatial cognition have been largely motivated by either an emphasis on males' and females' different reproductive roles and strategies or by their primary foraging activities in ancestral environments. These evolutionary frameworks account for many recognized sex differences in spatial cognition – such as the male advantage for wayfinding and mental rotation – and have been uniquely predictive of specific spatial tasks and contexts in which females outperform males (e.g., OLM). However, further research is necessary to determine the unmoderated extent of such sex differences, which adaptive pressure(s) caused their engrainment in human spatial cognition, and the processes in which these inherent differences interact with social, cultural, and experiential factors.

Sex Differences in Parenting

► Paternal Investment Relative to Maternal Investment

Sex Differences in Parenting and Parental Investment

Tetsuya Kawamoto

The University of Tokyo, Tokyo, Japan

Synonyms

Biparental care; Maternal investment; Paternal investment; Sexual asymmetry; Sexual dimorphism; Sexual selection

Definition

In many animal species, including humans, females tend to invest more heavily in their offspring than males.

Introduction

In general, parenting costs parents. As parenting usurps parents' resources, they may lose additional chances of mating and having children in the future. Many species, in fact, show no engagement in parental care (Alcock 2009). However, parenting might enable the offspring to succeed, survive, and reproduce, which offers larger benefits that outweigh the costs (Bjorklund et al. 2002). Many animal species, including humans, engage in parental care, although it is relatively rare among animals as a whole (Alcock 2009). Particularly in mammals, parenting is crucial for rearing an offspring, because mammalian babies are weaker at birth. Despite the necessity of parenting, males and females do not equally invest their resources in their offspring. There is variation among animal species in terms of the sex that primarily engages in parental care (Reynolds et al. 2002). Both males and females are apt to specialize in their parental care, often with a clear division of labor by sex (Clutton-Brock 1991; Emlen and Wrege 2004; Itzkowitz et al. 2001). In many cases, females specialize in caring for their

offspring and providing parental care much more than males do (Bjorklund and Pellegrini 2002; Geary 2000, 2010). These sex differences in parental investment can be explained by (1) anisogamy, (2) mating opportunity cost, and (3) paternity uncertainty.

Background

Although there are some species that do not provide parental care to their offspring, many animal species exhibit parenting behaviors. The level of parental investment provided by females and males varies according to species. In many species, females invest much more resources in their offspring than males do. Although parental care from males is relatively rare; paternal care, which generally includes provisioning and/or protecting an offspring, is observed in some species of birds, fishes, and insects (Perrone and Zaret 1979; Thornhill 1976; Wolf et al. 1988). For example, male birds often build nests and feed their offspring. Among some primates, carnivores, and rodents, males provide a great deal of parental care; however, they provide paternal investment in their offspring in less than 5% of mammals (Clutton-Brock 1991). In addition, many mammalian males often give care indirectly, such as by guarding crops. Moreover, parental care by males has been reported in many primates. According to these findings, males do provide parental care to their offspring, although male parenting is relatively rare (Hrdy 2000). However, sex differences in parental investment, namely, that females invest more heavily in their offspring than males do, are consistent for many species. Various factors have been alleged as reasons behind these sex differences: (1) anisogamy, (2) mating opportunity cost, and (3) paternity uncertainty. Each of these points is discussed below.

Anisogamy

Anisogamy refers to differences in reproductive strategies at the gamete level. The gametes of the sexes differ in size; they are larger in females than in males (Trivers 1972). Parental investment

theory holds that parental investment is a burden on parents. Various factors of life history relevant to the costs and benefits of caring and competing become specific to each sex. Therefore, Trivers' work implies that there are differences in parental investment between males and females.

Reproductive strategies might require resource allocation trade-offs between investments in mating effort and parental effort. For males, investing in mating efforts means mating with as many females as possible, which maximizes the number of offspring. Parenting effort involves investing resources, such as energy, time, and money, into a smaller group of the long-term mating partner and offspring, resulting in influencing the survival of the offspring. At the gamete level, as females produce eggs, which are much larger than male sperms, they have made a larger premating parental investment than males. In contrast, as males produce small, cheaper sperms rather than large, costly eggs, males are able to refill their gametes and more quickly go back to the mating market than females can. In other words, male ejaculations are considered smaller total amounts of gametic investment per mating than the gametic investment in the eggs released by females. Thus, the female bias in investment can be explained by the sex differences in gamete sizes that are a form of premating parental investment (Trivers 1972, 1983).

This phenomenon, that asymmetries in gametic investment are amplified to distinct sex roles in a self-reinforcing manner, is called sex-role divergence (Kokko and Jennions 2008). Trivers (1972) argues that two distinct interpretations might explain the divergence in sex roles. First, compared to males, females are more inclined to provide parental care, because females do not wish to lose their past premating investment. Second, compared to females, males are more inclined to compete for mates due to the male bias in operational sex ratio. Both explanations seem to partly account for sex-role divergence. However, neither is convincing in its association between sex differences in gamete sizes and those in parental investment (Kokko and Jennions 2008). Therefore, sex-role divergence in parenting remains an evolutionary difficult issue.

Mating Opportunity Cost

Parents put their reproductive energy into mating or parenting. As noted above, resource allocation between these two is a trade-off between current parental investment and future reproduction. The mating opportunity cost refers to the extra mating missed due to investment in the offspring. When both male and female are taking care of their offspring, it is quite difficult for them to mate with additional partners. The mating opportunity cost is considered a burden on both males and females. However, males bear a much greater mating opportunity cost than females, because the reproductive strategies by males depend on the availability of fertile females. If the number of fertile females is relatively high (female-biased operational sex ratio), males shift to investing their resources more into mating than parenting. If the number of fertile females is relatively low (male-biased operational sex ratio), males shift to investing their resources more into parental care. There are differences in trade-offs between mating and parenting among the Ache, a hunter-gatherer society in Paraguay, and the Hiwi, a hunter-gatherer society in southwestern Venezuela. Males among the Ache, who have a highly female-biased sex ratio, tend to invest their resources into mating efforts. In contrast, males among the Hiwi, who have a male-biased sex ratio, are likely to invest their resources into parenting efforts (Hurtado and Hill 1992). These findings are consistent with the notion that the mating opportunity cost of parental investment is much higher for males.

As just described, as males bear a greater mating opportunity cost in parenting than females do, males are less inclined to invest their resources into parental care than females. This notion leads to the expectation that male parental care is relatively rare when the mating opportunity cost of males is high (Alcock 2009). Conversely, when the mating opportunity cost of males is low, male parental care is favored. Thus, on an average, parenting and parental investment by males are less than those by females in many taxa. This theory of mating opportunity cost might also explain individual differences in parental care within a particular species. Differences in parenting among the Ache and the Hiwi are a good

example (Hurtado and Hill 1992). Pedersen (1991) investigated secular trends in human sex ratio and showed that male-biased sex ratios are associated with lower divorce rates (long-term mating strategies) and male willingness to commit care for their offspring. This finding is consistent with the mating opportunity cost theory.

Paternity Uncertainty

In nature, maternity is always certain; in other words, mothers are absolutely sure about their genetic contribution to their offspring. In contrast, paternity is never absolutely certain, that is, fathers can never be sure about their genetic relatedness to the offspring. This doubt regarding biological fatherhood is termed paternity uncertainty. In species that have concealed ovulation and/or internal fertilization, paternity uncertainty is a major problem for males. Due to internal fertilization, a new offspring might not be genetically related to a given male. Thus, possibly, males insidiously invest their resources into another male's offspring. The cost derived from misdirected parental investment makes paternal care less beneficial for males. Therefore, this asymmetry in parental certainty is conducive to sex differences in parental investment (Bjorklund and Shackelford 1999; Dawkins and Carlisle 1976; Geary 2000).

Paternity uncertainty has a relatively large influence particularly on human parental care. Since physical anthropometric traits are highly heritable (Canela-Xandri et al. 2016), greater similarity between a father and his offspring implies more paternity certainty. Therefore, fathers who perceive resemblance between themselves and their children are expected to provide more investment into parental care. In fact, perceived similarity between fathers and their children is correlated with emotional closeness (Alvergne et al. 2010) and with paternal investment (Apicella and Marlowe 2004) reported by fathers. These empirical findings support the notion that greater paternity uncertainty is associated with less paternal investment, which might cause sex-based differences in parenting and parental investment.

The foregoing mainly focus on the reduced amount of parental investment by males. On the

contrary, females are absolutely certain of their parenthood and have less mating opportunity cost than males. Due to these advantages of females, they should favor parental care. The primary caretaker hypothesis argues that the sex that cares more for an offspring will differentially obtain the skills necessary for parenting (Babchuk et al. 1985). For example, females, generally the primary caretakers, show a stronger preference for infants and a greater motivation to look after infants than males do (Charles et al. 2013). These female skills are evolved adaptations that enhance the odds of the survival of one's offspring (Babchuk et al. 1985). This primary caretaker hypothesis can clearly explain the intense, highly obligating maternal investment.

Conclusion

Parental investment by males is relatively rare, and even if males invest in parenting, the level of their investment is usually less than that of females. This sex difference in parenting and parental investment is found in many animal taxa. There are various reasons why males provide less parental investment in their offspring than females do. Anisogamy, the initial bioenergetic allocation of parental effort, might explain the sex differences in parental investment. In addition, sex differences in mating opportunity cost and in parental certainty might also give some account for the asymmetry in parental investment. Sex differences in parental investment embrace both the relatively low paternal investment and the generally abundant maternal investment. The arguments here generally focus on the relative amount of parental investment by males; however, the primary caretaker hypothesis might provide an account of female maternal investment.

²University of California – Los Angeles, Los Angeles, CA, USA

Synonyms

[Gender differences](#); [Gender schema](#); [Sex typing](#)

Definition

Because of societal expectations around gender roles, individuals generally engage in behaviors consistent with their gender role and avoid acts

that are not, leading to significant sex differences in participation within certain activities like politics, sports, and mathematics.

Introduction

Sex differences in participation have been found within many different domains of life, such as participation in politics, sports, and mathematics. While some contend that these discrepancies are due to biological influences and differences, they are often found to instead be the result of societal and cultural influences that enforce a strict gender dichotomy on individuals, pressuring people to only participate in those domains deemed “appropriate” for their sex while discouraging participation in domains regarded as “inappropriate” for their sex.

Gender Schema Theory

Introduced by Sandra Bem in 1981, the *gender schema theory* argues that societal forces construct strict gender roles that individuals learn from and adhere to, which become assimilated and passed down to other individuals within a culture. A schema is a “cognitive shortcut” or a tool that is used to process incoming information in a quick and efficient way. According to the gender schema theory, individuals are more likely to relate with information consistent with their gender schema and are quicker to identify gender-appropriate information. Consistent with this, individuals who complete the Bem Sex-Role Inventory (BSRI) rate characteristics that are consistent with their gender role as being more relatable to themselves than those that are inconsistent (Bem 1981).

The gender schema theory underlines society’s insistence on a gender dichotomy, labeling certain actions and behaviors as “feminine” and meant for females, while others are thought of as “masculine” and strictly for males to participate in. The gender schema theory has important

implications for human beings. As they begin to learn about societal constructs and gender roles, people internalize the characteristics and attributes that are believed to be “appropriate” for their gender and attempt to act in accordance with these. Individuals learn to assess their self-esteem and self-worth according to their conformity to the gender roles placed on them by society. People will often adjust their behavior and characteristics to ensure they are engaging in things deemed “appropriate” for their sex and refraining from things that are not, so as to avoid being condemned by society. Thus, gender schemas can lead to significant disparities in the participation of males and females in certain activities that may not be stereotypically “appropriate” for their sex (Bem 1981).

Sex Differences in Political Participation

Research has shown significant sex differences exist within participation in politics, with women thought of as being less involved in politics than their male counterparts. This discrepancy in political participation has led many to speculate on the potential reasons why: some say that socio-economic resources are less available to women, while others attribute it to societal constraints and gender norms that discourage women’s participation in politics, an often male-dominated field (Coffé and Bolzendahl 2010). However, this disparity brings into question whether these sex differences exist throughout all forms of political participation – maybe women do not necessarily participate less in politics, but rather they engage in politics differently.

Researchers Coffé and Bolzendahl (2010) investigated this question using data from the 2004 International Social Survey Program (ISSP) and examined men and women’s participation in four domains within politics: private political action, political party membership, collective activism, and political contact. The researchers found that women do not in fact participate less than men in politics, but rather they invest their efforts differently. Women participants were found to be significantly more

involved in private political action than men, which entails actions such as signing petitions, donating or raising money for political reasons, and boycotting and/or marching for political action.

Sex Differences in Sports Participation

It is undeniable that sports are often considered by many to be a masculine realm. However, too often this is considered to be the result of biological influences rather than societal and cultural influences – many individuals postulate that discrepancies between men and women’s participation in sports is attributable to physical differences that naturally put men at an advantage for participating in sports. While physical and biological differences between the sexes do exist, these differences do not adequately account for the significant sex differences within participation in sports (Chalabaev et al. 2013). Instead, it is necessary to consider the cultural and societal forces that contribute to such differences.

Gender norms and stereotypes have a significant influence on the sex differences seen in sports participation. Sports are often categorized as being masculine, feminine, or neutral, based on the percentages of each sex that participate in them; for example, soccer and football are considered to be “masculine” sports, while gymnastics and dancing are thought of as “feminine” sports. These “masculine” sports are often considered to be representative of what sports as a whole are – when asked to portray what sports and a sportsperson look like, both male and female adolescents drew pictures of a male playing soccer, indicating that this is the stereotypical representation of what sports *should* be. Such representations create a stigma around females who choose to participate in sports, especially “masculine” sports. Women who do choose to participate in “masculine” sports are often regarded as less “feminine” and aesthetically pleasing; these conceptions of women in sports frequently discourage their participation in such sports (Chalabaev et al. 2013).

Sex Differences in Mathematics Participation

Large sex differences exist within the field of STEM. Female adolescents, especially racial minorities, are significantly less likely to enroll in all mathematics-based AP courses, including computer science, calculus, statistics, etc. (College Board 2016). According to data collected by the National Science Foundation in 2010, women comprised only 27.5% of all STEM-related jobs (National Science Foundation 2010). Some have proposed that men are more represented and exhibit higher achievement within STEM because of intrinsic differences between males and females that favor men’s performance in mathematics. However, cognitive research has shown that there is no empirical evidence to support that either sex is inherently better than the other in terms of mathematics ability (Buckley 2016). Instead, empirical evidence has demonstrated that males and females have similar abilities within mathematics and learn mathematical concepts in the same ways (Spelke 2005). It is evident that women are significantly underrepresented within the STEM field and that these differences are not due to intrinsic capabilities, which begs the question: What contributes to these immense sex differences in participation in STEM?

A study conducted by Fryer and Levitt (2010) found that there were no differences between males and females’ achievement in mathematics when children first entered school; however, after 6 years of enrollment within school, significant sex differences emerged, with females displaying lower levels of achievement and participation compared to their male peers. Initially, some put forth the idea that men and women are neurologically different, enabling men to be “superior” at mathematics – however, this idea was proven to be ultimately unfounded, as there is not sufficient research supporting the idea there are profound differences between the male and female brain. Instead, these sex differences in mathematics participation seem to be the result of socialization rather than differences in

apptitude, such as differential treatment from teachers or parental expectations, with males' participation in mathematics being favored and encouraged while dissuading females from participating. Women appear to have as much aptitude as men for participating and succeeding in mathematics; however, socialization and gender stereotypes ultimately discourage women from entering and succeeding in mathematics (Fryer and Levitt 2010).

Conclusion

While it is unequivocal that sex differences exist within many domains of life, these discrepancies do not seem to exist because of inherent distinctions between men and women's biology. Instead, these differences are often attributable to societal influences and the process of socialization. Beliefs about the role of gender in society significantly contribute to what members of each sex decide to engage in, encouraging individuals to pursue things that seem "appropriate" for their sex and avoid those that are "inappropriate." In order to reduce sex differences in participation, it is important to treat men and women equally and try to avoid unconscious bias that discourages individuals from participating in behaviors solely because of their sex.

Sex Differences in Pursuit

Definition

Competition for achieving and maintaining positions of high social standing.

Introduction

Humans are group-living mammals, and our societies consist of stable dominance hierarchies,

defined as a set of relationships based on a structured ranking (Clutton-Brock and Huchard 2013). These social hierarchies can be either informal such as family units or formal such as governments or corporations. Obtaining a position of high status, i.e., an individual's prominence, respect, and influence in the eyes of others, should offer benefits to the survival and fitness of both sexes (Anderson and Kilduff 2009), for example, by leading to increased access to resources and mates – boosting survival and resulting in greater reproductive success. The route by which high social status is achieved, however, can be different for males and females.

Classic parental investment theory suggests that females should not be engaging in aggressive behavior for mate access due to the differential level of investment in offspring (Trivers 1972). Investment is defined as parental contribution which increases the offspring's survival at the expense of parent's future reproductive potential. As Trivers (1972) stated, "The sex whose typical parental investment is greater than that of the opposite sex will become a limiting resource for that sex. Individuals of the sex investing less will compete among themselves to breed with members of the sex investing more." (p. 140)

The typical mammalian pattern of parental investment places human females in the first category, concerned with resources and offspring survival, and human males in second, concerned with access to mates. Therefore, achieving status through aggression and displays of aggression should be a viable strategy for males, but not females. This plays out when one examines differences between male-male and female-female competitive strategies.

Male/Male Competition

While engaging in direct aggression may involve obvious costs such as physical injury or even death, an evolutionary cost-benefit analysis suggests that if the payoff is worth the cost, it's worth engaging in such behavior. For males, aggression displays have two reward outcomes – obtaining

status by winning the conflict and also as a demonstration of formidability level which should reduce the potential of other males risking an aggressive encounter.

Researchers have consistently found that human males are far more likely to engage in direct aggression in the pursuit of status, i.e., behavior intended to cause physical harm or pain, than females. This sex difference in aggressive competitive behavior begins at an early age and continues throughout puberty and beyond. Males are more likely than females to engage in physically aggressive acts during dyadic competition, i.e., one on one, and within groups, i.e., a gang (Campbell 2007).

Indeed, sex differences in aggressive status pursuit behaviors appear to be robust and consistent across the majority of human cultures (Campbell 2007) and may extend back at least 200,000 years (Keeley 1996). Evidence from the fossil record suggests that violent conflict may have been an important selection pressure for our evolutionary ancestors (Keeley 1996).

While it could be said that males are only engaging in physical aggression to protect themselves or family when under attack, apparently trivial motives for violent conflict such as mere verbal insults account for higher rates of aggression and homicide than any other reason (Daly and Wilson 1988). This suggests that the high costs of violence for males are offset by the potential long-term damage to a male's position within the hierarchy by ignoring a challenge, either verbal or physical. In a recent study of university students, 48 % of males stated status concerns as behind their last act of direct aggression (Griskevicius et al. 2009), suggesting that pursuing status through direct aggression is still a common strategy in current-day societies.

Female/Female Competition

According to Trivers (1972) as females need to remain healthy in order care for offspring, they are only expected to engage in direct aggression if the benefits, such as access to needed resources, far

outweighed the costs of risking their life and consequently their offspring.

It is wrong to say that direct female aggression does not occur. For example, in the previously mentioned study by Griskevicius et al. (2009), 45 % of females who had engaged in direct aggression also stated that the purpose was to defend their status. In general however, females avoid direct aggression where possible due to the high risk to themselves and the survival of their offspring (Campbell 2007) and instead rely on other tactics to pursue status, for example, indirect aggression.

Indirect aggression includes behaviors such as verbal critiques of another female's appearance, engaging in malicious gossip such as spreading rumors, and practicing social exclusion. These behaviors have been found to be most commonly directed against attractive and sexually available females and used as a weapon within competitions for status and mates (Vaillancourt 2013).

The strategy is to reduce the relative social standing and mate value of other rival females and thus boost their own. Research on mate preference has shown that males preferentially prefer young attractive females who are not promiscuous and a common indirect aggression strategy involves negative comments against a rival's appearance and spreading rumors about their sexual activity (Vaillancourt 2013). This derogation strategy is consistent with parental investment theory as it holds no physical dangers that could hamper their survival but is still an effective way of beating rivals and gaining status.

Dominance Versus Prestige

So far, the focus has been on the use of aggressive or dominance strategies to gain positions of status, but this is not the only way to ascend to the top of the human social hierarchy. Henrich and Gil-White (2001) have suggested that high social rank in human society can actually be reached by two distinct strategies: either by force, through threat or intimidation (dominance), or achieved freely

through demonstrating unique skills and knowledge (prestige).

In their paper on pursuing status in human social groups, Anderson and Kilduff (2009) presented a review of the evidence of status pursuit strategies that appeared to complement Henrich and Gil-White (2001)'s theory. They suggested that individuals in human societies don't necessarily attain status by bullying and aggressively intimidating others, but rather do it either by acting in a confident manner – and therefore suggesting superior competency – or by behaving in a generous manner, suggesting a commitment to the group as a whole, in other words, using prestige strategies to obtain status. However, Anderson and Kilduff (2009) failed to make any assumptions about whether there would be any difference in the use of this strategy between males and females.

One study by Cheng et al. (2013) helps to throw some light on this topic. Firstly, they found that both dominance and prestige strategies were equally successful in obtaining leadership positions and appeared to be used interchangeable by individuals, contrary to Anderson and Kilduff (2009)'s suggestions. Secondly, when the behaviors of men and women were analyzed separately, the effect sizes of the association between dominance and prestige and the measures of social influence were almost identical, i.e., there were no significant gender differences in the use of either strategies. This suggests that females and males are both adept at using forms of dominance and prestige strategies in the pursuit of status.

Conclusion

While both males and females actively pursue status, there is some difference in the methods they use to do so. Males are more likely to engage in acts of direct aggression to achieve and maintain status, while females use indirect aggression to belittle rivals and raise their own positions. However, when breaking status into prestige versus dominance, similarity appears between the sexes, suggesting that both sexes can flexibly use

a range of strategies in order to climb the ladder of our hierarchical societies.

Sex Differences in Same-Sex Aggression

Lee Copping

Durham University, Durham, UK

Definition

With few exceptions, males tend to exhibit higher levels of aggressive behaviors than females. This sex difference reflects differences in evolutionarily adaptive reproductive strategies based on mating versus parenting trade-offs, with males competing to maximize sexual access to females.

Introduction

Aggression and its intricacies are widely studied in the social sciences, and its potentially criminal nature propels it to the forefront of social policy development in modern society. Aggression is far from simplistic however, covering many different definitions, multiple subtypes, being criminal or noncriminal and is assessed by multiple measures. Indeed, Campbell (2005, p.68) goes as far as to say that aggression has historically been “taken to be innate and learned, universal and culturally prescribed, a pervasive trait and a contextualized response, functional and dysfunctional, behavioral and cognitive and a phenomenon not to be measured and modelled or experienced and described.” Internationally and historically, academics across disciplines have explored aggression from many perspectives, covering almost every aspect from its etiology to classifications of subtypes. Within all of this, perhaps the one most consistent element of this complicated behavior is the manifestation of universally stable sex differences. It is to this central theme that this chapter will be dedicated.

Evolution and Aggression

Few disciplines parsimoniously detail all of the intricacies of this phenomena as well as the

evolutionary sciences. Evolutionary psychology offers a theoretical framework from which testable hypotheses regarding a behavior can be generated. Thus, evolutionary psychology readily predicts sex differences across many domains of human behavior, aggression being one of them. It also provides a more parsimonious explanation as to the origins of the behavior than traditional social role-based theories. Note from the onset however that an evolutionarily driven theory does not imply determinism, and evolved, genetic mechanisms do not imply that certain cognitions or behaviors will be expressed. As shall be noted later, the environment plays a crucial role, providing important input to evolved mechanisms and consequently influencing their later output(s).

So why should sex differences in aggressive behavior be expected? Answering that requires an understanding of the purpose of aggression and the problem(s) that it emerged to solve. As our ancestors became the most dominant species on the planet and began to master many of the complexities of the earth's ecology, one of the most pressing threats to individual survival became each other. Conspecific competition became an issue that all men and women would have to cope with in order to maintain reproductive fitness. Competition is necessary to secure the resources required to survive. These resources can be material (food, shelter) but are not limited to this domain and include status and mate access. However, competition often entails the use of aggression and violence. It is an adaptive strategy that can be employed when necessary. Aggression can achieve many things: the acquisition of food, water, or territory, securing reproductive access to the opposite sex, defending against attackers, and eliminating threats to survival and reproduction. But this is not without limitations. Costs of aggression can be high, potentially catastrophic, including: the loss of resources, social ostracism, injury, or even death (eliminating the ability to reproduce permanently). Thus aggression is not necessarily the first response to a problem, and individuals carefully consider the costs and benefits of its use. While in some cases it may appear to be so, this decision-making process is not necessarily conscious, and our sophisticated evolved

neural architecture can manage this without explicit, conscious processes.

As competition is a fundamental part of life, necessary for both males and females, it is helpful to understand where the sexes are in fact similar where aggression is concerned. There are strong correlations between male and female aggression (including violent and/or criminal – Campbell et al. 2001). Male and female aggression levels are moderated by many shared environmental factors including: impoverishment, sex ratios, and population densities, to name but a few of the most common factors. Many underlying psychological mechanisms associated with aggression (traits such as anger, hostility, self-esteem) do not demonstrate the sex differences many would expect where aggression is concerned. Moreover, increasing levels of provocation decrease the magnitude of the sex difference in aggression (Archer 2004). The conclusion is thus obvious: male and female aggression is inextricably linked. The question therefore becomes, why should levels of aggression differ between men and women?

The Evolution of Sex Differences

Before examining why men and women should differ in terms of aggression, one must understand the differences in selection pressures they each face. The prevailing view in the evolutionary sciences for the basis of sex differences (not just in aggression) is one of differences in fitness variances. Two principles within the evolutionary discipline form the core explanation of many sex differences (across all species): sexual selection (Archer 2009) and parental investment theory (Trivers 1972). It should be noted that these two theories predominantly detail the benefits of male aggression. The costs and benefits of female aggression will be explored in section “[Explaining the Sex Difference: Male and Female Competition](#).”

The sex that makes the larger investment (predominantly the female) acts as a limiting factor for the sex with the smaller investment (predominantly the male). Investment in this

context means the allocation of bioenergetic resources critical for successful reproduction. Investment levels differ between males and females. For males, reproductive investment can potentially end at conception, meaning a strategy focused on accessing as many mates as possible can potentially grant greater fitness returns. For females, investment is protracted, entailing gestation, lactation, and resource acquisition to sustain any resulting offspring (potentially for many years post-pregnancy). While males can quickly reenter the mating arena and repeat this process with as many other females as they can access, females cannot usually do so for some time after birthing, creating a skewed operational sex ratio with an excess of reproductively active males.

Directing resources to parenting is generally more advantageous for females to ensure reproductive fitness, despite the resource burden of reproduction reducing their overall reproductive rate. The sex with the lower rate of reproduction thus benefits more from parenting than mating. Male reproductive rates can be much higher given low obligatory costs that females must bear. Despite low reproductive rates, however, a female is rarely unable to mate, thus reducing their reproductive variance. Females (who bear the real costs of reproduction) aim to maximize their investments and usually seek high genetic quality or the offer of high levels of male offspring investment from potential partners. For males, there is no ceiling on reproductive rate. This, however, is contingent on males competing for sexual access to mates, either through female choice or aggressive intrasexual competition. As such, while females are nearly assured to have mating opportunities, the risk of reproductive oblivion for males is much higher. Consequently, reproductive variance is much higher for males than for females. According to Trivers (1972), "The sex whose typical parental investment is greater than that of the opposite sex will become a limiting resource for that sex. Individuals of the sex investing less will compete among themselves to breed with members of the sex investing more" (Trivers 1972, p.140).

Consequently, fitness variances between males and females shape sexual strategies. Males

compete for females, and females strive to access high-quality males. Male competition in particular fostered sexual dimorphisms that enhanced their reproductive success. Indeed, it appears that across species (including our own), greater variability exists for sexually selected traits rather than nonsexually selected traits in males and females (Archer and Mehdikhani 2003). To take an example from the animal kingdom, the northern elephant seal's (*Mirounga angustirostris*) physical size is a sexually selected characteristic through which it establishes social dominance. Large males more ably monopolize access to females and defend against (or remove entirely) subordinate male rivals. Mate competition is intense, with over 75% of all seal pups being the resulting offspring of approximately 5% of adult males. Furthermore, merely 10% of males actually survive to reproduce at all. As if the competition was not enough for males, female elephant seals deliberately attempt to mate with the most socially dominant and "protest" against the advances of subordinate males. This further increases male-male conflict and allows females to effectively choose the best mates. Physical size in the elephant seal thus allows males to compete while simultaneously acting as a signal of quality to females, increasing the likelihood that the largest males reproduce and increase their overall fitness. Sexually dimorphic traits have evolved in hominid species also, such as facial hair, voice pitch, and physical size, and likely evolved as a result of inter- and intrasexual selection (Archer 2009). Furthermore, archaeological evidence suggests that aggression can increase male fitness benefits (Grauer and Stuart-Macadam 1998).

From the principles of sexual selection and parental investment theory, testable hypotheses regarding the expression of behaviors or traits can be generated. In the case of aggression, the following predictions can be made:

1. As reproductive variances are higher for males than for females, so to should variances in sexually selected behaviors such as aggression.
2. As males compete for female access, aggression should be more often invoked by males than females.

3. Ecological factors such as density, resource scarcity, and sex ratio should increase levels of aggression.
4. Aggression (and any subsequent sex differences) should be universal across all cultures and time periods.
5. Levels of aggression should increase through development, reach its zenith during the most reproductive phase of the lifespan, and decline with increasing age.
6. In our evolutionary past, males who use aggression successfully should achieve fitness gains.
7. The magnitude of the sex difference should increase as the behavior becomes increasingly violent and dangerous.

The discussion above has touched on data pertaining to hypotheses 1, 3, 4, and 6, and there is relative consensus that aggression is likely a sexually selected trait (Archer 2009). The remainder of the chapter is dedicated to detailing where human men and women differ in terms of aggressive behavior.

How Do the Sexes Differ in Terms of Aggression?

As the mating arena poses different challenges for men and women, it is reasonable to predict that they will express aggression differently. Research confirms this, with males being ubiquitously more aggressive. Gender differences appear in almost all forms of aggression, and this effect appears universally across age, time, culture, and geography. Numerous meta-analyses have confirmed these effects (e.g., Archer 2004). This provides further evidence to support hypotheses 2 and 4: that males should resort to aggression more than females and that this effect should be consistent across cultures. As noted earlier, aggression has multiple forms, subtypes, and categorizations, and it is impossible to cover all of them here. The most obvious place to start, however, is with an analysis of sex differences in direct aggression.

Sex Differences in Direct Aggression

Direct aggression represents the propensity to intentionally inflict either physical and/or psychological harm or injury or reputational damage upon another person and can be physical, verbal, violent, nonviolent, criminal, or noncriminal. In all cases, the target can identify the aggressor and is able to retaliate immediately. As such, direct aggression is a strategy of high risk, and the costs of such an action can be high. It is also the type of aggression in which the differences between men and women are most pronounced, supporting prediction 7 which suggests that the sex difference should increase in line with increasingly violent or dangerous aggressive behaviors.

Across almost all measures of direct aggression, men universally express higher levels of it (Archer 2004, 2009) and show greater variation within it (Archer and Mehdiakhani 2003). While men and women are more likely to aggress against members of the same sex, men are most likely to be the victims of aggression, not just from other men but also from women (Archer 2004). Physically aggressive activity (such as hitting, kicking, etc.) show male-biased effect sizes between $d = 0.91$ and $d = 0.59$, with smaller effect sizes for nonphysical aggression such as abuse and threats, $d = 0.46$ and $d = 0.28$ (Archer 2004). Men are more likely to aggress toward known, rather than unknown, targets, but lowering aggression in line with greater levels of intimacy, while females report more aggression toward unknown than known targets. Females are more likely however to aggress toward an opposite sex intimate partner than males (to be discussed later).

Homicide is overwhelmingly male biased, with 97% of killings involving men and 99% of same sex homicides being male-male (Daly and Wilson 1988). The likelihood of hospitalization through violence induced harm is significantly higher for men than women (Shepherd 1990). Approximately three quarters of violent offences committed by women, however, are classed as simple assaults (Greenfeld and Snell 1999). Men are much more likely to carry and aggress with weapons (Archer 2004), while women fight mainly with their fists and/or feet (Ness 2004). Pathologies characterized by high levels of

aggression, violence, and criminality tend to be heavily male biased (American Psychiatric Association 2000). Consistent with the theory of sexual selection and parental investment, introducing the motivation to mate appears to increase direct aggression in men but not women, with this increase directed predominantly at the most viable same-sex targets such as single, unmarried men (Ainsworth and Maner 2014). Sex differences appear very early in childhood, often observable from 12 months of age (Baillargeon et al. 2007), and while the actual magnitude of these differences remain relatively stable until the early teens, male aggression then begins to peak (Archer 2004). Throughout adulthood, this difference remains but declines in magnitude with age. These data provide support for prediction 5 with aggression being at its highest levels during our core reproductive years.

Sex Differences in Indirect Aggression

Indirect aggression is conceptually ambiguous, often used synonymously with terms such as relational and social aggression. Here, indirect aggression is used to cover all of these subsets, following Archer and Coyne (2005) who claimed these terms are best integrated due to their conceptual overlap. Indirect aggression is more veiled than direct aggression and is used as an alternative way to harm the target, for instance, via manipulating other people to conceal one's own identity. It includes actions such as gossiping, rumor spreading, ostracism, and defamation and acts where the perpetrator often remains anonymous to victims. Indirect aggression is a low-cost attack on a target. It is also a type of aggression relatively unique to our own species, with analogous behavior in animals being almost nonexistent (Archer and Coyne 2005).

Meta-analytic studies to date suggest that in this domain, sex differences do not exist, with either trivial effect sizes in the female direction or parity between the sexes (see Archer 2004). However, variation between these studies is considerable (potentially due to measurement issues), and, while the precise nature of the sex difference within indirect aggression remains inconclusive, there are specific sex differences noteworthy of

discussion. This provides us some support for prediction 7, as in the case of indirect aggression, sex differences are difficult to detect due to the inherently nonviolent nature of the behavior.

Research shows that girls preferentially used indirect aggression compared to boys (52% versus 20%, respectively, in 15-year-olds) when comparing engagement rates. Women also show stronger preferences for this strategy (even after controlling for perceptions of social norms and approval). Girls rate these forms of aggression as more harmful than boys (Coyne et al. 2006). In the media, indirect aggression is likely to be enacted by an attractive female aggressor, the characters often portrayed as justified for and rewarded by its use. Girls who exhibit higher levels of indirect aggression watch such programs more than less-aggressive peers, and viewing this form of aggression appears to increase its use by girls in real-world settings (Archer and Coyne 2005). Gossip patterns also vary between males and females. While both sexes attend more to same-sex gossip, this effect is stronger in women, who engage in more of it and also remember more details regarding other women who were subject to it, particularly if the victim is physically attractive. The use of exclusion tactics is more prevalent in girls than boys, appearing in some form from as young as age three and persisting into adolescence and adulthood (Benenson 2013). While aggregations on a meta-analytic level do not display consistent sex differences, particular subtypes, when examined individually, demonstrate differences favoring women.

Sex Differences in Other Aggression Related Areas

Unsurprisingly, there are sex differences in a number of psychological areas pertinent to aggression. Men and women mentally represent their beliefs about aggressive behavior differently. Beliefs and justifications, or social representations, separate into two distinct dimensions: instrumental (believing aggression is a means to an end) and expressive (believing aggression results from loss of control). Men are more likely to view aggression instrumentally while women are more expressive (Tapper and Boulton 2004).

Differences in social representations of aggression emerge in childhood from an early age (Tapper and Boulton 2004). Instrumental beliefs tend to show a positive correlation with verbal and physical aggression. Expressive beliefs however show more inconsistent patterns of results with actual levels of aggression (Tapper and Boulton 2004). Representations also demonstrate relationships with forms of noninjurious outbursts of angry behavior.

Males and females also differ on unconscious levels when it comes to aggression. Noted earlier was the male propensity to aggress with weaponry (Archer 2004). Related to this, men are also more sensitive to the presence of weapons (Sulikowski and Burke 2014). From early childhood, men even report higher frequencies of aggression and violence in dreams than women, and within dream manifestations of these aggressors are far more likely to be male (Schredl 2009). Finally men and women are more likely to form false memories regarding aggression in a way consistent with sex differences in actual aggression. Laney and Takarangi (2013) demonstrated using false feedback procedures that men were more likely to form false memories about causing a black eye while women were more likely to form false memories about spreading malicious gossip. These reflect the differences observed in direct and indirect aggression. While these more unconscious elements of aggression receive less empirical attention in the literature, it is the nonetheless interesting that they exist and that the evolved minds of men and women process information on the periphery of aggressive behavior differently, but not irreconcilably so from the actual expression of aggression itself.

Explaining the Sex Difference: Male and Female Competition

So why should men be so much more likely to attack, wound, and kill each other compared to women? Why should women prefer a more circuitous form of aggression? These two important questions require answering in order to truly understand why the sexes differ. Referring back

to the earlier discussion on differences in reproductive variances, the answer becomes apparent. For men, the reproductive stakes are high and the drive to compete is more imperative. Men compete for mating opportunities with women, and aggression allows men to establish dominance hierarchies, suppress challengers, and remove threats to reproductive success. For men struggling to access mates, the impetus to aggress increases, as failure to mate means lineage extinction. Although potential costs are high, men will risk injury, and potentially death, in order to achieve fitness gains. As the alternative is to not reproduce, however, the potential reward of reproductive success becomes all the more salient. Combine this impetus with ecological disadvantages, such as an operational sex ratio with more men than women (making access harder), lack of status or resources to attract women (making them less desirable than the competition) or high concentrations of young men (who particularly lack the status and resources of older, more experienced conspecifics) and the overall likelihood of male-male competition increase further. Reproductively active men become more accepting of the risks involved in aggression, and this increases the frequency and magnitude of male aggression. This phenomena was termed by Wilson and Daly (1985) as the “young male syndrome.” Note that this competition for female access is not necessarily conscious and indeed is not usually directly about aggressing over women. Men fight over status and their overall position in the dominance hierarchy. The hierarchy symbolizes their worth to women and thus their desirability as a mating prospect (recall the example of the elephant seal). Thus it is status that, in the environment of evolutionary adaptiveness, would have translated into reproductive success and it this that they are willing to use aggression to achieve and maintain.

Status acquisition in males begins early in development. Hierarchical structures appear in groups of boys as early as age six. The position a boy occupies is even predictive of their dominance 9 years later. Rough and tumble play is more important to and engaged in more by boys, allowing them to establish who is tougher. Boys more than girls are also better at identifying who

among a group is the strongest (Archer 2009). This early development of competitive behavior suggests boys are effectively preparing themselves for status competitions that will emerge in young adulthood. While high-status men will not necessarily be more aggressive, the pursuit of status from those who seek it may necessitate aggressive strategies to retain it. Group living has fostered norms that punish aggression in most cases, and status can be awarded in a variety of other ways such as demonstrating wealth or excelling in competitive sports. However, men can use aggression in certain circumstances to gain status if they can maintain an image of strength and of credible threat to challengers. Men are particularly sensitive to attacks on status and position (Daly and Wilson 1988), and the need to defend it results in violent escalations and retaliations to “save face.” This is one reason why many male-male altercations begin with startlingly banal causes (jests, jostling, insults, etc.) and can ultimately lead to homicide. Despite the risks entailed in escalation, the potential loss of status is too great a cost, and aggression often ensues to prevent it.

Many authors (see Campbell 2013) note that this explanation of sex differences in aggression focuses almost exclusively on why men should aggress and not on why women should. According to Triver’s principles, females aggress less simply because their likelihood of not reproducing is comparatively lower. But women are also locked in their own competitive struggles which may manifest in aggression, if not necessarily as often or as directly as men (Benenson 2013; Campbell 2013). It is important to explain when and why women will resort to physical force if necessary. As with men, status loss and the avoidance of victimization are prime motivations. Women who successfully fight can force other women to withdraw and establish a reputation to disincentivise challengers (Campbell 2013; Ness 2004). As with men, these reputations often require defending. Retaliation over insults, particularly those deriding either their sexual reputation or attractiveness, are also key determinants of aggressive escalation in women (Campbell 2013; Ness 2004). A second motivation in women stems

from jealousy and the need to protect an existing relationship, or the status that such a relationship may bring (Campbell 2013; Ness 2004). These escalations likely increase in situations where there is variation in men’s resources or a general paucity of males exists, making competition for well-resourced mates (even in the short term) worth fighting for. While these are pertinent explanations of why women physically aggress, they do not explain why women’s aggression is lower in magnitude when compared to men. As noted earlier however, there are distinct sex differences in indirect aggression that clearly favor women, and in understanding these, an explanation as to why women are less likely to resort to physical aggression becomes clear.

The so-called young male syndrome claims that men take risks to achieve status that translates into fitness gains. But, women rarely fail to find a partner: their fitness is thus not at stake in the same way. However, the tactics employed by males affect females in other ways. Male investment in offspring is low as men often aim to invest more time in mating effort rather than parenting (Trivers 1972). Consequently, males do little to no child rearing, largely due to the fact that a male can never be 100% sure that an infant is his; cuckoldry is after all a potential risk. To reinforce this point, note that the loss of a father (and thus his provisioning power) has little impact on offspring fitness (Sear and Mace 2008). Thus, the survival of children depends almost exclusively on continued investment from mothers. Research shows that this is the case across human societies (Sear and Mace 2008). The optimal use of a women’s resources is therefore to ensure continued investment in her children. If the mother was harmed in such a way that she could not adequately provision her family, her children’s survival (her inclusive fitness) would be endangered. Were she to die, the consequences would have been likely fatal to the offspring, and lineage extinction would be increasing likely (Campbell 2013). Thus, women benefit from staying alive, because this, ultimately, will keep her children alive as well. Given the importance of survival of the mother to survival of the offspring, selection pressures should favor less costly means of competition in women.

Women however still need to compete (not just indirectly) despite potential costs. They still require resources to survive and provision. They still aim to access higher-quality males for reproductive purposes (and aim maintain access for as much investment as possible). Their propensity to aggress also increases as males aggress, driven by the same environmental factors that heighten competition and make survival harder. The necessity for women to use aggression does not disappear in the face of rising costs. Female aggression, however, still entails higher costs than the equivalent action in males, and this should translate into a less confrontational style of competition. If an opponent cannot retaliate, a woman may be able to increase the survival odds in favor of her own progeny. Indirect aggression provides a means of achieving this end.

This explains why most indirect aggression (1) shows a female bias, (2) from females, is predominantly aimed at other females, (3) is used primarily during adolescence and young adulthood (the peak reproductive window for females and when competition for mates is most salient, Vaillancourt 2013), and (4) increases in females when mating motivation is experimentally primed. These elements of indirect aggression parallel the major trends demonstrated earlier in same-sex male direct aggression. There is therefore a growing consensus that indirect aggression is an intrasexual competition strategy among women (Benenson 2013; Campbell 2013).

From an early age, women, like men, form dominance hierarchies between themselves. Dominance hierarchies in females confer fitness benefits such as higher offspring survival rates (Campbell 2013). A woman's status can be based on a number of factors such as her mate value, her alliances with other females, and the status of her mate(s) and/or kin (Benenson 2013). Other women act as a barrier to achieving reproductive goals, and so female-female competition tends to be disguised, aims to punish other females who strive for similar goals, and potentially leads to the elimination of unrelated females via exclusion tactics (Benenson 2013). High-status women also have a competitive edge and can compete more overtly, either through their

mate value or alliances, as the threat of retaliation from lower status targets is less likely (Benenson 2013). Women do not necessarily need to cause direct physical harm to other females in order to inhibit their reproductive success. Character defamation and rumor spreading, particularly regarding a woman's sexual reputation, are seen as successful aggressive tactics designed to reduce the status of females in the community, as female mate value is often contingent on sexual fidelity (Vaillancourt 2013). Similarly, attacking another woman's appearance can reduce the target's attractiveness as a mate to men and as an ally to other women. This explains why name calling (such as "slag" and "slut" or "ugly" and "fat") is perceived as more damaging to women and why this may result in escalation to physical retaliation (Campbell 2013; Ness 2004) as they are challenges to a woman's mate value. These escalations are still much lower in magnitude (and in their consequences) than typical male-male aggression as, in the vast majority of circumstances, fitness costs remain much higher than reproductive benefits. Avoiding direct conflict (and thus harm) for the sake of offspring survival is still a safer strategy for women (Campbell 2013).

Risk and Fear

Two key elements have been identified in this analysis of sex differences – the salience of risk in pursuit of reproductive reward to males and the avoidance of high costs in safeguarding reproductive fitness for females. Sexual selection theories focusing on male risk-taking as a driver of aggression (Wilson and Daly 1985) are complementary to theories regarding female avoidance of direct aggression (Campbell 2013). As the propensity of the sexes to accept risks differs, with women being more avoidant than men, risk-taking could be a proximal mechanism that mediates the sex difference in aggression.

It is thus not surprising that sex differences in risk-taking are evident and in directions that parallel sex differences in aggression. Men have significantly higher scores on measures of risk-taking and sensation seeking than women across

almost all measurement types (Byrnes et al. 1999; Cross et al. 2011). The magnitude of this sex difference increases with the potential costs (Byrnes et al. 1999). In tasks involving rating situations on the level of risk entailed, women's estimates are significantly higher than men's (Eagly and Steffen 1986). Furthermore men and women classified as greater risk-takers and sensation seekers exhibit aggressive behaviors more frequently (Wilson and Scarpa 2010). Measures of risky impulsivity completely mediate the sex differences in physical and verbal aggression. The parallels between aggression and risk-taking are suggestive of a potential link.

If sensitivity to risk drives human aggression, what motivational factors, for women in particular, curtails this trait? Campbell (1999, 2013) suggested that the underlying driver of sex differences in risk and aggression can be reduced to an evolved sex difference in fear-based inhibition. Risk-taking (and synonymous measures such as sensations seeking) can broadly be classified as the reverse of fear. Strong emotional responses to fearful stimuli are likely to inhibit the urge to take risks. If this is so, sex differences should be evident in this domain, with women experiencing it more strongly than men. Campbell's review of the evidence suggests that this appears to be the case, with levels of fear being significantly higher for women being observed cross-culturally while reporting to experience it more intensely. Girls also express fear developmentally earlier than boys. Psychometric analyses of measures containing items with fear and anxiety connotations show gender differences in the female direction, while indices of sensation seeking lacking elements of danger show no sex differences. This fear-based mechanism may be specific to real physical danger, as there are few sex differences in measures that examine social fears only. Research also indicates that fear appears to more strongly suppress aggression in women than in men, while harm avoidance is a significant mediator in the relationship between gender and expressive representations of aggression. A wealth of neuropsychological evidence supports the proposition that differences in sensitivity to fear is perhaps the underlying mediator of

gender differences in aggression. Neuroimaging studies show that subcortical structures such as the amygdala (located in the temporal lobe) and the orbitofrontal cortex may be pivotal in managing responses to fearful stimuli. Wider and longer activation patterns of the limbic system (which includes the amygdala) are evident in women who are presented with threatening stimuli. Similarly, sex differences are evident in response to angry, threatening faces. Orbitofrontal activation is also greater for women than for men in response to facial stimuli that express negative emotion. Similar relationships between the orbitofrontal cortex and the amygdala have been reported previously in aggressive individuals, which may suggest that women show higher levels of restraint and more effectively regulate negative emotions.

These sex differences in fear may explain one of the intricacies of aggressive behavior, the somewhat unexpected sex differences found in intimate partner violence or IPV (Cross and Campbell 2011). While most homicides resulting from IPV are committed by males (Daly and Wilson 1988), this is largely a function of the fact that men are much stronger and kill more generally. Jealousy accounts for a much larger proportion of female-perpetrated homicides than male-perpetrated homicides, suggesting that, as males are physically larger and stronger, the higher number of male perpetrated partner deaths may just be a factor of their greater physical ability to kill rather than jealousy led motivation. Thirty-five percent of IPV-related injuries are sustained by men, while a meta-analysis of IPV measures (based upon different acts) found a small but significant effect in the female direction, suggesting that females are more likely to aggress toward partners than vice versa. Female aggression toward partners is also not only limited to minor acts. Cross-culturally, even allowing for national levels of female empowerment, men are more likely to be victims of IPV (Archer 2006). However, women do not just aggress toward men generally, it appears only disinhibited toward men they are intimate with. This suggests that there is something specific to intimate partner dyads that may invoke a muted fear response.

So why are women more likely to attack intimate partners than other men (or women) generally? Campbell (2010) suggests this could be due to fear reduction in women who are emotionally invested in their partners. In this model, the non-peptide hormone oxytocin (which is secreted during and has a functional role in several bonding, nurturing, and sexual behaviors) serves to reduce the level of fear and stress in females. Forming a sexual relationship requires a female to decrease inhibitions. As selection pressures on female mate choice make choosing the wrong partner a costly business, it is advantageous for females to be more generally inhibited sexually to allow time to choose appropriate partners carefully and to reduce the risk of injury from sexually aggressive partners. The release of oxytocin thus serves as an anxiolytic to the fear that normally inhibits sexual behavior and allows copulation to occur. The effect of oxytocin is likely to be one of general disinhibition to facilitate mating but potentially disinhibiting aggression as a by-product. Campbell cites evidence suggesting that oxytocin release increases during interactions with a partner simply increase the odds that a female may be more likely to aggress toward them as opposed to strangers and explains this reversal of the sex difference in IPV. This functional account of oxytocin moderated changes to fear-based inhibition allows us to reconcile why women may be more aggressive than men in intimate situations in a way that is still entirely consistent with complementary evolutionary explanations. It should be noted, however, that recent work challenges this hypothesis in finding that the administration of oxytocin can cause fear reductions in men and the opposite effect in women. Further work is required to comprehensively understand the wider implications of oxytocin as well as how it may act differently within the male and female brain (Campbell 2013).

Conclusion

Understanding aggression as an adaptive response provides a functional purpose for both the behavior and the gender differences within it. Contrary

to popular belief, aggression is not a pathology and is a strategy that all are capable of under specific conditions to facilitate survival. It is essential that we understand how the sexes differ if we are to have a full understanding of this broad phenomenon, and this review represents only a small fraction of the research conducted in the field to date. While the underlying psychology of the sex differences in aggression is not wholly clear, the recent advances in theory regarding fear-based inhibition (Campbell 2010, 2013) go a long way in reconciling why men and women appear more or less aggressive across different situations. Although these theoretical developments contingent on models of oxytocin and evidence from small scale neuropsychological studies are in their relative infancy, research stimulated by these newer ideas and continued advances in neuroscience will no doubt enhance our understanding of the neuromechanisms responsible for the universal behavioral differences observed between men and women.

Gender is equally pivotal for the purposes of policy and intervention in aggression, violence, and crime. We must understand how and why men and women act and react differently if any degree of success is to be expected from strategies society implements to reduce these potentially dangerous characteristics. Much of this work also needs to focus on what we know to be the shared antecedents of aggression, namely, environmental factors that increase the likelihood of competition: poverty, lack of educational opportunities, population densities, and social and gender inequalities. This is by no means a small task, but greater work is required to examine how these various factors impact strategies that include aggression (Copping and Campbell 2015). Finally, it is worth reiterating that much of the historic literature has focused on predominantly male aggression. While this has been vital to our understanding of behavior, it is encouraging to note that there is an increase in work focusing on female aggression (Benenson 2013; Campbell 1999, 2013; Cross and Campbell 2011). As noted earlier, women are not passive compared to men in their use of aggression and have their own reproductive agenda to which aggression can

be used to pursue. Future work should continue to integrate accounts of male and female aggression into their theoretical underpinnings in order to help advance the field constructively.

Sex Differences in SDO

Gender differences in SDO

Definition

Gender predicts social dominance orientation (SDO) such that men typically express higher levels of SDO than women.

Introduction

Research across a wide variety of cultures has provided a great deal of evidence showing that

men, compared to women, have generally higher levels of social dominance orientation (SDO), an individual difference variable reflective of support for unequal, hierarchical relationships between groups. Although the sex difference in SDO is relatively well established in the literature, the questions of (i) how contextually invariant the relationship between sex and SDO is and (ii) what underlies this sex difference in SDO contribute to an ongoing debate among scholars.

Sex and SDO

Social dominance theory (SDT; Sidanius and Pratto 1999) states that the purpose of group-oriented social hierarchies is to reduce conflict between groups and maintain human survival over time. According to SDT, individuals differ in their preference for hierarchical group-based systems of inequality, with this preference being termed “social dominance orientation” (SDO). Individuals high on SDO endorse group hierarchy and believe that groups do and should differ in status and power, whereas individuals low on SDO endorse group equality and oppose differentiation of groups based on status and power (Pratto et al. 2000). This individual-difference variable is assumed to have its origin in both cultural (socialization) and biologically influenced factors (Sidanius et al. 1994).

The gender hierarchy is one of the most prominent group-based hierarchies in societies around the world. Gender has been found to consistently predict SDO with men as members of the higher-status group expressing higher SDO than women as members of the lower-status group. Men’s greater expression of SDO compared to women’s helps in explaining the existing gender difference in women and men’s attitudes in a wide range of sociopolitical domains (see Pratto et al. 1997). For example, women are more politically liberal than men (e.g., Feather 1977) such that they express less prejudice (Ekehammar et al. 1987) and authoritarianism (Altemeyer 1981) and show more support of social equality (Ekehammar and Sidanius 1982). In addition, women have less punitive attitudes than men (e.g., Ekehammar

1985), and they are more likely to favor policies that support the disadvantaged (e.g., Shapiro and Mahajan 1986).

SDO and the Gender Invariance Hypothesis

Men’s greater scores in SDO compared to women’s is one of the most consistent findings in research examining SDO and has led to the formulation of the *gender invariance hypothesis* (Sidanius et al. 1994). The gender invariance hypothesis asserts that, *all else being equal*, gender differences in SDO will be found such that men will exceed women in SDO scores and that this difference will be relatively universal and invariant across cultural, social, and situational factors. Sidanius et al. (1994) however differentiate between a strong and a weak version of the invariance hypothesis. According to the strong version, the gender difference in SDO should remain invariant across cultural factors, situational factors, or both – i.e., no significant interaction between sex and cultural-situational factors should be found. In contrast, according to the weak version, the gender difference in SDO might vary somewhat across certain cultural-situational factors, but women should not exceed men on SDO scores – i.e., sex might interact with cultural-situational factors, but this interaction will always be of ordinal and not disordinal nature.

The gender invariance hypothesis has been supported by numerous studies including student and general-population samples that produced one of the most robust findings in SDO research even when considering a range of covariates and moderators (e.g., Pratto et al. 2000; Sidanius and Pratto 1999; Sidanius et al. 1994). Some scholars have however challenged the gender invariance hypothesis (e.g., Huang and Liu 2005; Schmitt et al. 2003; Wilson and Liu 2003; Zakrisson 2008). For example, Wilson and Liu (2003) found an apparent cross-over interaction between sex and gender identification such that women with low levels of gender identification have higher SDO scores than men with low levels of

gender identification, whereas men with high levels of gender identification have higher SDO scores than women with high levels of gender identification. These findings however were criticized by Sidanius and Pratto (2003) who argued that the “*ceteris paribus*” principle of all else being equal was violated and stated that the “analysis is about as meaningful as comparing female members of police death squads (hierarchy-enhancers) with male social workers (hierarchy-attenuators), a comparison also likely to find women with higher SDO scores than men” (p. 210). Wilson and Liu (2003), in both studies, however also included gender identification as a covariate instead of a moderator in additional analyses and found that the previously significant sex difference in SDO disappeared. Other scholars also obtained evidence inconsistent with the gender invariance hypothesis. For example, when women and men were exposed to a majority of female members in voluntary associations (Zakrisson 2008), or when ethnic rather than gender identity was made salient (Huang and Liu 2005), men and women did not differ in SDO scores. Cross-cultural research also sometimes failed to show the expected sex difference (e.g., in two out of six samples, see Pratto et al. 2000). Taken together, the inconsistent findings regarding the relationship of sex with SDO shows that the dispute about the gender invariance hypothesis is far from being settled.

Causes for Sex Differences in SDO

According to the biocultural interactionist perspective, biologically influenced factors (e.g., temperament, personality) as well as cultural factors (e.g., socialization) contribute to individuals’ SDO (see Sidanius et al. 1991, 1994). Greater SDO in men than women is seen as important for the male reproductive strategy, where dominant groups of males aim to monopolize female reproductive resources (Sidanius and Pratto 1999). Gender-role socialization into typically female roles, such as teacher, nurse, or children’s caretaker, requires concern for other people, which is negatively correlated with SDO. In

contrast, gender-role socialization into typically male roles, such as police officer, soldier, or manager, requires a willingness to dominate other groups with legal means or violence (Pratto et al. 1994). The “gendered” roles of caretaker and war maker are consistent across cultures and might also contribute to explaining the consistent sex difference in SDO and the invariance hypothesis (Pratto et al. 1997).

Some scholars however feel that this biocultural interactionist perspective is too backward looking and that it leads to “SDO being an outcome of the past rather than the present” (p. 805; Batalha et al. 2011). These scholars therefore favor a cultural-deterministic perspective and more immediate situational explanations for the presence or absence of sex differences in SDO (e.g., Batalha et al. 2011; Huang and Liu 2005; Schmitt and Wirth 2009; Wilson and Liu 2003). From a cultural-deterministic perspective, the invariance hypothesis should not hold as any sex differences in SDO are the result of a specific gendered socialization pattern, culturally transmitted gender roles and self-stereotyping, and contextual or environmental factors. For example, demonstrating the importance of context rather than gender, Batalha and colleagues found women and men to differ in SDO when the ideologies that they were exposed to sanctioned values that promoted group hierarchy. In contrast, the authors found that men and women converged in their SDO beliefs, when these ideologies were minimized.

Conclusion

Gender is one of the most consistent predictors of SDO with men typically exceeding women in their preference for group hierarchy and for differentiation of groups along the lines of status and power. The question to what extent this sex difference is invariant is part of a lively scholarly debate and awaits further careful and systematic investigation of the “all else being equal” principle of the gender invariance hypothesis. In addition, scholars also cannot definitively conclude the origin of the sex difference in SDO,

but they found considerably evidence that SDO is related to a large number of gender differences such as mating strategies, occupational role, and political attitudes. Future research might shed further light on the questions of *why* and *when* examined “gendered” preferences for group hierarchy are stable or malleable as a function of the context that we are socialized and embedded in.

Definition

How the social environment influences males' and females' expression of sexuality and gender identity.

Introduction

Sexual socialization is a process by which an individual develops his or her own identity by acquiring the skills, knowledge, and values of the gender they prefer (Schneewind 2001). In most societies, women are viewed as communal, warm, gentle, kind, and passive, whereas men are viewed as tough, aggressive, and assertive (Huddy and Terkildsen 1993). This entry will explain in further detail the differences between the socialization of gender roles and how they affect males and females differently throughout the lifespan.

Parental Influence

Parenting is one source of sexual socialization. There are a number of studies that have highlighted sex differences in communication between parents and their children. For example, conversations between fathers and adolescent sons typically contain more topics on sexual activity than mothers and adolescent daughters (Nolin and Peterson 1992). However, adolescent males and females report that their fathers tend to be less available for personal conversation than their mothers, and fathers have reported experiencing significantly more discomfort than mothers when discussing topics of a sexual nature with their children (Nolin and Peterson 1992).

When it comes to sexual behavior, parents often treat their daughters differently than their sons. It has been noted that parents' communication with their adolescent daughters is often conducted in an effort to control their daughter's sexual behavior (Nolin and Peterson 1992). In fact, "mothers give their daughters important cues about desirable appearance and body image, which may have implications for self-sexualization" (Starr and Ferguson 2012, p. 465). This is not the case with male children. It has also been theorized that mothers who possess high levels of self-objectification as well as low levels of religiosity can cause early sexualization in their daughters (Starr and Ferguson 2012). Belsky, Steinberg, and Draper

theorized that without the presence of a father in the child's early life, parenting expectations are not reliable whereas those with the presence of fathers in their early years develop a different kind of expectations about the nature of others (Belsky et al. 1991).

There are other cultural variables to be considered when socially constructing gender in society. These factors include the relative status of men and women, the division of labor by gender, fathers' involvement in caregiving, economic opportunities, and religious beliefs and values (Best and Williams 1997).

Cultural Influences

Gender roles and stereotypes are culturally constructed. As early as 2 years old, males and females have a gender preference (Leaper and Friedman 2007). Girls are likely to favor feminine, domestic toys such as dolls, cooking sets, and dress-up materials, while boys prefer masculine toys such as cars, trucks, tools, and sports equipment (Leaper and Friedman 2007). Toys create this expression of what is socially acceptable to boys and girls. Young girls will imitate their dolls by wearing makeup or similar clothing, not understanding that these items influence the socialization between males and females (Starr and Ferguson 2012). In addition, some research has also shown that young females will favor sexualized dolls over non-sexualized dolls (Starr and Ferguson 2012). Similarly, video games intended for young males hypersexualize women by accentuating the female physical characteristics and dressing them in promiscuous clothing (Starr and Ferguson 2012). Young males are also exposed earlier to the idea of self-efficacy with toys reinforcing constructive goals (e.g., LEGOs and Lincoln Logs) (Block 1983).

Gender stereotypes are commonly used in children's television shows. Many of these shows perpetuate the idea that men hold a higher status than women due to overrepresentation of males (Leaper and Friedman 2007). Sexualized models on television, magazines, and music videos are appealing to young females, which can lead

young females to pursue behaviors and styles that resemble what they see in popular culture (Starr and Ferguson 2012).

Scharrer's (2013) content analysis research suggested that television disproportionately values thinness in females and males. She also noticed there was consistency with media characters thinner than the rest of the population, where just 24% of women in the population met the clinical definition of "thin" according to the US Center of Disease Control (Scharrer 2013). In an evolutionary perspective, extreme thinness does not show fertility, rather a lack of. These are two diametrically opposed ideas, where society suggests thinness is standard, and in evolution, women were selected by their bodies based on fertility. Television is an influential source of information from which modern day children often develop ideas regarding how men and women differ in physical appearance, domestic roles, gender roles, and occupation (Scharrer 2013).

Bandura's social learning theory is where individuals learn either by observation or direct experience (Bandura 1971). He emphasizes that actions are governed by reward and punishments, where it is an individual's free will to carry out these actions (Bandura 1971). Children learn reward and punishment at home by their parents. Peers influence each other as young as 2 years old when it is the appropriate time that mothers take their child to daycare. Evolutionary theories look to explain why girls would naturally behave passively in the presence of boys. Females paired with males displayed more passive behavior and a significant decrease in social interaction with the opposite sex (Jacklin and Maccoby 1978).

Abusive Influence

Some psychologists have argued that children who experience sexual abuse may exhibit advanced sexual behavior in their adolescent years (Finkelhor and Browne 1985). When children are rewarded for sexual behavior, they learn to use this behavior as customary to manipulate others to satisfy their needs (Finkelhor and

Browne 1985). Adolescent boys who have been victims of abuse can be sexually aggressive towards their peers (Finkelhor and Browne 1985), which may be a symptom of a distorted idea regarding what is considered appropriate social behavior.

Verbal, mental, physical, and emotional abuse can have lasting effects into adulthood that may cause problems in one's daily life. Victims of abuse may experience traumatic memories, dislike for sex, or sexual dysfunction (Finkelhor and Browne 1985). As the abused child matures, he or she may experience problems in their adult relationships. Some have argued that those who have been abused are more likely to become the abusive adult (Finkelhor and Browne 1985).

Some researchers have suggested that female victims of domestic violence are more likely to bare male children (Kanazawa 2006). Although this stance is controversial, Kanazawa's (2006) data supports this theory. Violent men seem to produce more male offspring than female offspring, and violent men produce more male offspring than nonviolent men. However, the cause of this correlation is unknown. It is uncertain whether this increase in male offspring production is caused by the violent men (i.e., violent men produce more male offspring) or by the victimized women (i.e., battered women produce more male offspring). Regardless of the cause, if this phenomenon is true, then these children may be socialized by their violent parent to display aggressive behaviors.

Conclusion

Children can acquire skills and knowledge regarding gender identity via social learning (Bandura 1971). This social learning can be the product of parents, peers, and/or media influence. Regardless of the source, "... the child becomes motivated to seek similar positive outcomes by imitating the rewarded behavior" (Starr and Ferguson 2012, p. 464). Children learn through their environment and often adopt these gender roles based on what they believe is considered socially acceptable. In the first years of life, parents hold a strong

influence over this socialization process because children spend most of their time with their parents. As children grow into adolescents, peers and other environmental influences begin to play an increasingly larger role in sexual socialization. However, research also shows that not all aspects of gender identity and sexual socialization are caused by social influence (Kahlenberg and Wrangham 2010) so research in this area is still needed to fully understand this phenomenon.

Sex Differences in Sexual Versus Emotional Jealousy

- [Sex Differences in Jealousy](#)

Sex Differences in Short-Term Mating Preferences

David P. Schmitt¹ and David M. Buss²

¹Brunel University London, Uxbridge, Middlesex, UK

²Department of Psychology, University of Texas at Austin, Austin, TX, USA

According to Sexual Strategies Theory (Buss and Schmitt 1993), our species comes equipped with numerous mate preference adaptations. Some are specially designed for *short-term mating*, including mechanisms guiding how often and with whom we prefer to engage in casual sexual encounters and extra-marital affairs. Some short-term mate preferences differ between men and women. Men tend to desire easy sexual access when short-term mating and functionally relax

their desires to create more opportunities for consummation. Women, in contrast, are relatively selective when short-term mating. Two leading hypotheses for the function of female short-term mating are the “good genes hypothesis” (e.g., preference for hypothesized good genes markers such as symmetry, masculinity, and physical attractiveness) and the “mate switching hypothesis,” using affairs as a strategy to exits one mating relationship, evaluate potential alternative mates, or re-mate with a more beneficial or less cost-inflicting partner (Buss et al. 2017; Buss and Schmitt 1993).

Evidence of Women’s Specialized Short-Term Mating Psychology

Survey studies document women tend to particularly prefer physical attractiveness in short-term mates compared to long-term mates (Buss and Schmitt 1993; Buunk et al. 2001; Gangestad and Simpson 2000; Kenrick et al. 1990). Regan et al. (2001) found women rated physical attractiveness 7.80 on importance in short-term mate choice, but only 6.32 in long-term mating (on a 9-point scale). Castro and Lopes (2011) found women prefer a “pretty face” 3.42 in short-term mates, but only 2.17 in long-term mates (on a 5-point scale), and women prefer a “beautiful body” 3.08 in short-term mates, but only 1.83 in long-term mates.

Supporting the “good genes” view of women’s short-term mating psychology, women emphasize specific physical attributes much more in short-term mating than long-term mating, such as facial symmetry, facial masculinity, large muscles, and other testosterone-related cues (Johnston 2006; Waynforth et al. 2005). Women also report physical attractiveness-related *motives* for short-term mating 24% of the time (in men it is only 10%; Regan and Dreyer 1999).

Women more often choose and more strongly react to physical attractiveness in their *actual* behavior within short-term mating contexts. For instance, women tend to have affairs with especially symmetrical men (Gangestad et al. 2005), and women have more frequent and consistent copulatory orgasms with physically attractive

men (Puts et al. 2011). Women are judged more likely to consent to short-term mating with a male stranger if he is high in physical attractiveness (7%), compared to only moderate physical attractiveness (3%) or low physical attractiveness (2%) (Schützwohl et al. 2009). When approached by *actual* strangers in real life situations, women tend to say “yes” to a real stranger’s query “will you go to bed with me?” if the man is high in physical attractiveness (3%) versus only average in physical attractiveness (0%; Guéguen 2011). In a Danish study, whether women said yes to an actual stranger’s asking for sex was influenced by the physical attractiveness of experimental confederates (Danish men were not so influenced; Hald and Høgh-Olesen 2010). Evidence suggests men’s physical attractiveness matters to women in their real-life casual sex experiences involving short-term mating.

If women are to maximally gain the “good genes” benefits of selective short-term mating, they would be most effective at choosing attractive men for casual sex when the women are nearing ovulation (the time of maximum conception probability). Several studies have found women’s preference for physical attractiveness in potential mates peaks around ovulation (Thornhill and Gangestad 2008). Women’s preferences for men who have facial symmetry, body masculinity, vocal masculinity, and social dominance all peak around ovulation (Gildersleeve et al. 2014). These findings are especially true if women are of low mate value and if a woman’s husband is physically unattractive (hence, her adaptive need for “good genes” is intensified; Pillsworth and Haselton 2006).

Another useful tool for evaluating women’s short-term mate preferences is to compare women who engage in a lot of short-term mating to women who are exclusively long-term maters. Women who engage in more short-term mating during their lifespan tend to emphasize physical attractiveness, masculinity, and interpersonal dominance more in mate choice (Gangestad et al. 2005). Women high in unrestricted sociosexuality (i.e., short-term oriented women) tend to perceive smiles as flirting (much like most men do, Howell et al. 2012). If single, women high in

sociosexuality prefer especially masculine men (whereas already-mated women do not; Sacco et al. 2012). Women who are more likely to engage in short-term mating tend to prefer men who possess masculine attributes (Frederick and Haselton 2007) even including the way masculine men walk (Provost et al. 2008). In summary, women who actively engage in short-term mating are more likely to exhibit the short-term mate preferences hypothesized by Sexual Strategies Theory

Women may engage in short-term mating for a variety of adaptive reasons (Greiling and Buss 2000), not just to obtain good genes from physically attractive men. Women can benefit from confusing their partners about paternity, from directly obtaining resources, from obtaining physical protection of multiple males, from evaluating their own mate value, and from the potential of a short-term mating experience to lead to a long-term mateship. For instance, women engaged in short-term mating tend to prefer men who provide immediate resources (especially as opposed to men who just have future resource *potential*; Buss and Schmitt 1993), and men are typically judged more effective in short-term contexts when they provide immediate resources (Schmitt 2002). Resource levels are closely related to age, and in a study of 25 year olds (Buunk et al. 2001), researchers found women tend to prefer short-term mates who are older than themselves by about 4 years (age 29, with an average maximum acceptable age of 38), whereas men prefer women of about 1 year younger as short-term mates (age 24, with an average maximum acceptable age of 31). The typical findings in studies of prostitution (e.g., Bonnerup et al. 2000) and pornography consumption (Hald 2006) also support the view that women more often than men engage in short-term mating in exchange for resources. In short, there is some empirical support for the resource acquisition function of women's short-term mating.

Evidence has been accumulating for the mate switching function to explain why mated women have affairs (Buss et al. 2017). The findings include: (1) women who are emotionally and sexually dissatisfied with their regular partner tend to

have affairs; (2) women tend to fall in love with their affair partners, (3) women perceive mate insurance and trading up to a better mate as a key benefit of affairs, and (4) women's mate preferences for affair partners mimic closely those they desire in long-term committed mates (see Buss et al. 2017 for summaries and citations). None of these findings are well explained by the good genes hypothesis but are well explained by the mate switching hypothesis. Falling in love with an affair partner, for example, would interfere with the dual mating strategy of securing genes from one man while securing investment from another. The two hypotheses, of course, are not mutually incompatible. It is possible that some women pursue a dual mating strategy while others use affairs for a mate switching function.

Men's Specialized Short-Term Mating Psychology

Evolutionary psychologists have hypothesized men can reap strong reproductive benefits from engaging in short-term mating. Indeed, as the lesser-investing sex in terms of gametes (Bateman 1948) and obligatory parental investment (Trivers 1972), men should be more eager than women are for opportunistic short-term mateships and should be less discriminating than women in their selections of casual sex partners. Several sources of evidence have confirmed these fundamental features of men's short-term mating psychology (see Schmitt 2014).

One source comes from surveys that ask men and women the degree to which they eagerly desire short-term mating. In 1993, Buss and Schmitt asked a college student sample the extent to which they were *currently seeking* short-term mates, the *number of sex partners* they ideally desired at limited time intervals into the future, and whether they would *consent to sex* with someone they viewed as desirable if they had known the person for limited amounts of time. In nearly every instance, men more eagerly desired and more quickly consented to short-term sex than women did. Schmitt et al. (2003) replicated these findings across more than 10,000 college students

representing 10 major regions of the world. Sex differences in self-reported desires for short-term mating are likely a pancultural universal (see also, Lippa 2009).

An important caveat to these findings, however, is that many men report they are relatively uninterested in short-term mating. Evolutionary psychologists do not expect all men to be eager for short-term mating at all times. Instead, only some men eagerly pursue short-term mating strategies, especially those who can successfully pursue the strategy given their own physical attractiveness, status, and overall mate value (Gangestad and Simpson 2000). Early attachment experiences, local pathogen levels and sex ratios, and heritable differences also influence the degree to which men pursue short-term mating as a sexual strategy (Schmitt 2016). For example, considerable evidence suggests when there is a surplus of women in the mating pool, men are inclined to shift to a short-term mating strategy and become more reluctant to commit to a single partner (Buss 2016). The logic of Sexual Strategies Theory suggests that *when* men pursue short-term mating, they do so guided by evolved desires that are different from the desires of women who pursue short-term mating. Men who short-term mate tend to desire more numerous mating partners, be quicker to consent to sex, and more eagerly engage in brief sexual encounters compared to women who short-term mate. A wide variety of data sources supports this view (Buss and Schmitt 2011).

Beyond simply asking men and women the extent to which they eagerly desire short-term mating, *per se*, sex differences exist in numerous sex-related attitudes and behaviors closely associated with short-term mating. For instance, men have significantly more positive attitudes than women toward casual sex, permissive sexuality, and emotion-free sexual experiences (Petersen and Hyde 2010). Carroll et al. (1985) asked men and women if they always needed to be emotionally close in order to have sex with someone, with 45% of women and only 8% of men responding they required emotion for sex. Also asked was the somewhat awkward question of whether they would *never refuse a sexual offer*, with 46% of

men saying they would never refuse a sexual offer, but not a single woman (0%) reporting she would never refuse a sexual offer. In the context of short-term mating, evidence suggests that *all* women are at least somewhat selective, whereas about half of men apparently have quite low minimum standards.

In a meta-analysis of 30 sexuality-related attitudes and behaviors, Petersen and Hyde (2010) found men had more positive attitudes toward casual sex ($d = 0.45$) and toward sexual permissiveness ($d = 0.21$). Men were also more likely to engage in extra-marital sex ($d = 0.33$) and casual sex ($d = 0.28$). Petersen and Hyde (2010) erroneously reported that “most gender differences in sexual attitudes and behaviors were small” (p. 21), but this was not true for sex differences in eagerness for short-term mating, nor is it true for evolutionary psychology’s many predictions concerning mate preferences (which were empirically ignored by Petersen and Hyde). Indeed, many sex differences in mate preferences hypothesized by Sexual Strategies Theory are rather large in size, far exceeding the effect sizes typical in psychology.

In 1991, Simpson and Gangestad developed a measure of a trait called sociosexuality. This measure was specifically designed to assess whether someone is willing to have sex without commitment (i.e., is sociosexually unrestricted). Across every sample that has ever been studied, men report more unrestricted sociosexual attitudes and behaviors than women (Schmitt 2005). Schmitt (2005) assessed the sociosexuality of men and women across 48 nations and found men were more unrestricted than women in every culture (average $d = 0.74$). In 2009, Lippa replicated Schmitt’s results across a larger sample of 53 nations, including exactly replicating the overall sex difference of $d = 0.74$.

Emotionally, men tend to experience less regret than women do after engaging in short-term sex or “hook-ups” (instead men particularly regret *missed opportunities* for short-term mating; Bradshaw et al. 2010; Galperin et al. 2013). Men also tend to over-perceive sexual interest from opposite-sex strangers more than women do (Haselton and Buss 2000; Perilloux et al. 2012);

men tend to want, initiate, and enjoy a wider variety of sex practices than women do (Baumeister et al. 2001); and men tend to have higher general sex drives in all cultures that have been studied (Lippa 2009).

Men generally relax their mate preferences in short-term mating, whereas women *increase* their selectivity in short-term mating, especially for physical attractiveness (Gangestad and Simpson 2000; Kenrick et al. 1990). Men, but not women, also prefer short-term mates who are easily sexually accessible. In an experimental study, men found women who give cues to “easy sexual access” as more attractive for short-term mating but not for long-term mating, and women showed no increased attraction toward easily sexually accessible men in any mating context (Schmitt et al. 2001).

Although men *self-report* that they value and desire large numbers of short-term sex partners more than women do, it is possible such findings do not reflect what men actually do when offered short-term sex. In studies of actual mating behavior, however, men are more likely than women are to consent to sex with a stranger (Clark and Hatfield 1989; Hald and Høgh-Olesen 2010; Schützwohl et al. 2009). In 1989, Clark and Hatfield had experimental confederates approach college students across various campuses and ask if they would like to have sex. Around 75% of men agreed to have sex with a complete stranger, whereas no women (0%) agreed to sex with a complete stranger. Twenty years later, Hald and Høgh-Olesen (2010) largely replicated these findings in Denmark, with 59% of single men and 0% of single women agreeing to the proposition, “Would you go to bed with me?” Interestingly, they also asked participants who were already in relationships, finding 18% of men and 4% of women currently in a relationship responded positively to the request.

Schützwohl et al. (2009) asked participants to judge what men and women would do in a similar situation, but they also manipulated the physical attractiveness of the confederate. For men, they were thought to agree to sex with a stranger if she was highly attractive 54% of the time, whereas women were thought to agree to sex with a

stranger if he was highly attractive 8% of the time. Guéguen (2011) had confederates of various levels of physical attractiveness *actually* approach real-life strangers and ask if they would have sex, finding 83% of men agreed to have sex with a highly attractive woman and 60% of men agreed to sex with a woman of average attractiveness. For women, 3% agreed to have sex with a highly attractive man, but no woman (0%) agreed to sex with a man of average attractiveness. As noted earlier, men of high physical attractiveness are most able to successfully pursue a short-term sexual strategy. For the average-looking man, short-term mating may not represent a viable reproductive option.

Numerous studies have confirmed that men are more likely than women to engage in extra-marital sex (Petersen and Hyde 2010) and short-term mate poaching (i.e., seeking short-term sex partners who are already mated; Schmitt et al. 2004). Behaviorally, men are more likely than women to pay for short-term sex with (male or female) prostitutes (Bonnerup et al. 2000). In a Danish study, 16% of men and no women (0%) reported that they had “ever had sex with a prostitute?” (Bonnerup et al. 2000). Men are also more likely than women to enjoy sexual magazines and videos containing themes of short-term sex and sex with multiple partners (Salmon and Symons 2001).

Conclusion

According to Sexual Strategies Theory (Buss and Schmitt 1993), our species comes equipped with specialized adaptations (including mate preferences) that profoundly influence on our appraisal, desire, pursuit, and selection of mates. The evolved mate preferences that drive men and women when pursuing short-term mating strategies differ in fundamental ways. When short-term mating, men preferentially desire easy sexual access and relax their desires so as to obtain large numbers of sex partners. Women’s short-term mating is likely more complex. Leading functional hypotheses include selection for “good genes” as part of a dual mating strategy,

mate switching, and resource acquisition, all of which could be correct for some women in some contexts. Much remains to be explored in the evolutionary psychology of human mating, but at present the evidentiary status of most sex differences in short-term mate preference adaptations postulated by Sexual Strategies Theory, evaluated using multiple lines of evidence as advocated by Schmitt and Pilcher (2004), is both broad and deep.

Synonyms

Boy and girl social learning; Early male and female socialization; Early relationship processes

Definition

The alternative socialization processes in childhood that enhance and solidify male and female stereotypic behavior.

Introduction

From the very beginning of childhood, social structures facilitate and influence evolutionarily constructed sex differences to emerge and become strengthened as children become older. This social development is tailored to enhance sex differences and prepare each sex for competition in mating strategies once they reach sexual maturity and into adulthood. It begins at home with parental socialization, and then moves into peer groups, with most socialization coming from same sex peer groups. These same sex peer groups often mirror the same sex parental socialization found in the home. Ultimately, this lays the foundation for the types of relationships each sex will end up having, with boys having greater and more inclusive social networks based on competition and social dominance hierarchies and girls having smaller and more intimate relationships based on self-disclosure. This then plays itself out in terms of the different mating strategies and forms of competition each sex finds itself in when they reach sexual maturity and adulthood. This entry will discuss the major social factors that differentially influence the socialization of sex differences during childhood.

Parental Socialization

Cross-cultural research has demonstrated that a very large and important sex difference arises early in childhood, especially when children are raised in cultures that are not socially restrictive – namely, that boys tend to be more assertive and dominant, whereas girls tend to be more nurturing and empathic (Schmitt et al. 2008). Part of the reason that these sex-typed characteristics emerge so early is in response to differential parental reinforcement or punishment of sex-typical behavior. For instance, shyness is a personality characteristic that would undermine the valued assertiveness characteristic in boys, but not the valued nurturing and empathic characteristics of girls. Indeed, Simpson and Stevenson-Hinde (1985) found that for 3.5–4-year olds, parents reacted to girls' shyness with positive behaviors

like acceptance, whereas for boys parents expressed concern and fear for their future.

In addition, parents of boys and girls tend to vary in their use of discipline in regard to their child's early interaction with others. As early as age two, parents of girls react to their child's struggle over an object with another child by stressing the importance of perspective taking and prosocial behavior while relinquishing the object to the other child, whereas parents of boys tend to favor their son's claim to the object much more often (Ross et al. 1990). Thus, parental encouragement and intervention early on in childhood works to enhance sex stereotypic traits, emphasizing communal relationships in girls and independent and dominant relationships in boys. Much of this parental involvement is in preparation for the same-sex peer socialization that is to become a major influence in the further delineation of sex differences.

Same-Sex Peer Groups

Young children tend to naturally segregate themselves into same sex peer groups, and the time spent socializing with same sex peers tends to increase as the child grows older (Maccoby and Jacklin 1987). As noted by Maccoby (1988), much of the reason for this increasing peer segregation is based on the interaction styles that are prevalent for each sex and the lack of responsiveness each sex has toward the social style of the other. Young boys tend to utilize the assertive and dominant tactics that are inherently stereotypic and were reinforced by parents, whereas young girls tend to focus their social style on promoting intimacy and equality. These social styles produce very different peer group structures that further exacerbate these sex differences.

The social structures of boys tend to be large and complex, with emphasis on dominance hierarchies and ingroup cohesiveness, whereas the social structures of girls tend to be more dyadic in nature, with emphasis on self-disclosure and personal connections (see Geary 2010). These group dynamics and associated group behavior plays a significant part in preparing each sex for

engaging in competition for mates when older. The social styles of each sex contributes to the size and complexity of group dynamics namely in regards to the cost and rewards of utilizing each style in reference to the size of groups. The assertiveness of boys lends itself well to intergroup competition and the formation of social hierarchies, whereas the tender-mindedness of girls lends itself to intimate dyads. Geary et al. (2003) notes that the fundamental difference is the ease by which boys' ingroup competition allows for larger groups, which allows for better intergroup dominance. The low level of interpersonal investment allows for group growth and maintenance. On the other hand, the emotional investment required in girls' dyadic relationships preclude the formation of larger and more interconnected ingroups – the costs are merely too high. This difference is highlighted in research examining the formation of male and female peer groups during camps that lasted for several weeks (Savin-Williams 1987). At the end of these camps, boy peer groups tended to be very strong, large, and inclusive with increased stability over time. Conversely, girl peer groups tended to be decreasingly stable with time, as they became segmented and fractured into smaller dyads.

Ultimately, as Geary (2010) explains, the larger and more dense social networks of boys create opportunities to engage in competition and learn the dynamics of social hierarchies, which will provide them with a framework for competitive interactions in the future with other males over resources and access to females, while also providing a necessary foundation for ingroup formation that is essential for intergroup competition. In this way, boys can individually find their place within the ingroup social hierarchy and remain committed to the group's goals given the stability of male ingroups. The smaller and more intimate dyadic relationships of girls play an entirely different function in the preparation for adult interactions. Girl relationships require much more emotional investment but also are much less stable and more prone to deterioration. In the end, though, the benefits of girls relationships in terms of self-disclosure and social support help prepare

girls for deep relationships with other women in adulthood.

More importantly for girls, however, is the knowledge gained regarding social relationships and their mechanisms, which confers benefits to them and their eventual offspring. These benefits include assimilation into the mate's social structure and gaining strong social support with that social structure from other women, as Geary (2010) proposes that boy and girl social strategies partially arise in response to the tendency of ancestral females to emigrate into the ancestral males group, leaving behind their previous modes of social support. Furthermore, in the competition for mates the social skills gained through intimate relationships allows females to use social manipulation and relational aggression to put themselves in a more advantageous position to acquire a mate (Crick and Bigbee 1998). The depth and intimacy of female relationships also mirrors the level of investment required for reproductive purposes and subsequent care for the offspring, something that is not required of males according to the parental investment theory (Trivers 1972).

Conclusion

Overall the natural sex differences that exist are met with a confluence of socialization influences that help strengthen those sex differences and prepare boys and girls for their separate paths toward relationships and mating strategies. Parental differences in socializing sex stereotypic behaviors are evident from infancy, and once children become old enough to interact with peers they often segregate themselves into same sex peer groups, which exacerbates sex differences by the formation of different types of groups built on different styles of interaction. Boys tend to be more directly assertive in their interaction style, which helps create large and interconnected social networks built on competition and social dominance hierarchies. Girls, on the other hand, tend to be more inclined toward cooperative and intimate interaction styles, which require large amounts of resources and investments into

relationships, thereby producing smaller interaction groups more characterized by dyads. This combined parental and peer socialization facilitates the type of relationships typically exhibited by each sex in adulthood and contributes to differences in mating strategies as well.

Ultimately, the large social networks of boys help establish competition within the group for dominance and subsequent access to the more valued female counterparts, but also cooperation in response to outgroup competition which helps the group as a whole to overcome outside threats and secure resources. The smaller social networks characteristic of girls then helps not only to increase knowledge of intimate relationships, but this knowledge increases the ability to form close relationships with other females when emigrating into a new social structure, as females may have historically been more likely to move into their mate's social group. Finally, this level of intimacy and nurturing that has been cultivated through early female social interaction greatly assists with the extensive investment requirements of reproducing offspring and caring for that young. Together, sex socialization in early childhood is a dynamic force that enhances innate sex differences in order to best formulate relationships and contribute to the next generation.

Definition

Differences between males and females in the faculty that processes neural representations of physical space, such as the orientation and movement of objects.

Introduction

Spatial ability (SA) is an overarching concept for a wide range of abilities that involve neural representation and manipulation of physical space. Examples include wayfinding, running, jumping, and ballistic feats, such as hitting game in hunt or enemies in warfare, as well as the invention and construction of machinery, writ large. While human (gonadal) sex differences in cognitive abilities are generally small, males systematically and substantially outperform females on tests of SA, with meta-analytic effect sizes in the range 0.48–0.94 (Linn and Petersen 1985; Voyer et al. 1995; for reviews, see Hirnstein et al. 2019; Zell et al. 2015). Such tests include judgments of how gravity affects liquid in a vessel, judgments about how objects are rotated in two- or three-dimensional space, and understanding of the operation of cogwheels, pulleys, and gears.

Real-World Significance

Domains that involve spatial processing tend to exhibit the largest sex differences in terms of average performance, interest, and the proportion of males to females involved in professions to which such abilities are central (Lippa 2010b; Valla and Ceci 2014; Wai et al. 2018; Su and Rounds 2015). Examples of such professions include controlling tools and vehicles (e.g., aircrafts, cranes, excavators, trucks, and submarines) mechanical construction and repair (e.g., buildings, roads, bridges, and infrastructure in general), engineering and the STEM fields in academia (Peers 2016), and ball games and other sports that involve spatial ability, such as shooting and racing (partly reviewed in Li 2014). Specific performance differences include furniture assembly (Wiking et al. 2016), wayfinding in real terrain (Silverman et al. 2000), and chess (Blanch et al. 2015).

SA and mathematical ability are correlated even when intelligence has been controlled for, particularly for higher levels of mathematical problem-solving ability (Casey et al. 1995). This suggests that SA is important for even more

abstract cognitive performance that involves mental manipulation of quantities and relations, such as in chemistry, physics, and computer programming (for reviews, see Heilbronner 2013; Valla and Ceci 2011; Berenbaum and Beltz 2016; Lippa 2010a).

Etiology of Sex Differences in Spatial Ability

Sex differences are present before puberty, extant studies beginning at 8–9 (Gur et al. 2012, Fig. 4) to 10 years of age (Linn and Petersen 1985), and increase across puberty and into adulthood (Barel and Tzischinsky 2018; Gur et al. 2012). It has been suggested that androgens mediate genetically influenced, adaptive sex differences that originate from natural or sexual selection pressures (Lynn 1994). Consistent with this theory, SA is not related to prepubertal androgen exposure, in terms of the androgen marker of 2D:4D digit ratio (Hampson et al. 2008), but to adult androgen levels in both sexes, such as testosterone (Barel and Tzischinsky 2017; Christiansen and Knussmann 1987). Specifically, females' SA increases with testosterone over the natural variation in the menstrual cycle (Celec et al. 2002; Harrison 2000), is increased by administration of exogenous testosterone (Aleman et al. 2004; Pintzka et al. 2016), and is elevated in females with congenital adrenal hyperplasia, a condition in which females become masculinized due to incorrect steroid metabolism (for reviews, see Hampson and Rovet 2015; Puts et al. 2008). Associations between masculinity/femininity and SA suggest that sex roles mediate the effects of sex (Signorella and Jamison 1986; Reilly et al. 2015; a recent meta-analysis is found in Reilly and Neumann 2013). On the other hand, this may be a trivial effect of natural variation in physiological masculinization in both sexes (Berenbaum and Beltz 2016; Puts et al. 2008; Halari et al. 2005).

Conclusions

It has been suggested that sex differences in spatial abilities constitute evolved adaptations

that reflect division of labor in ancestral, hunter-gatherer ecologies (these arguments are summarized in Silverman et al. 2007). SA may therefore be a particularly useful trait for investigating heritable and adaptive mechanisms by examining relations between sex, masculinity/femininity, and other variables (for overviews of this field, see Gur and Gur 2017; Berenbaum and Beltz 2016; Valla and Ceci 2011).

Sex Differences in Variance Traits

Satoshi Kanazawa
London School of Economics and Political
Science, London, UK

Synonyms

Sex differences in standard deviation; Sex differences in variability; Sex differences in variance

Definition

Members of one sex (male or female) have significantly greater dispersion or variability on a trait than members of the other sex. They contrast with sex differences in the mean of a trait.

Introduction

In statistics, the *mean* (or median or mode) is a measure of central tendency, whereas the *variance* (or standard deviation) is a measure of dispersion. Scientists commonly study mean differences between groups, when one group has a higher (or lower) mean level of a trait than (an) other group(s). As a result, most statistical techniques and tests of statistical significance involve the mean. It is less common for scientists to study group differences in variances, and there are fewer statistical techniques and tests of statistical significance that involve the variance. Nevertheless, scientists sometimes focus on group differences in variances because they are of theoretical or empirical importance, and sex differences in variance are no exception. Sometimes men exhibit greater variance in a trait; other times (though less frequently), women exhibit greater variance in a trait.

Potential Causes of Sex Differences in Variance

There are at least two potential causes of sex differences in variance: genetics and polygyny. For the most part, both of these factors function to produce significantly greater variance among men than among women.

Genetics: X Chromosome

Males of mammalian species (including humans) have an X chromosome and a Y chromosome in their genome, whereas females of such species have two X chromosomes. This means that any phenotype (observable trait) that is coded in the X chromosome is an expression of one X chromosome among males and an expression of two X chromosomes among females. When the phenotype is an expression of one gene (housed in one X chromosome for males), it has greater variance than when the same phenotype is an expression of two genes (housed in two X chromosomes for females). This is because the expression for the female is the average of the two genes, whereas the expression for the male is a singular value. Statistically, the average of two values is always more likely to be closer to the overall mean of the distribution (and thus is less variable) than a singular value.

Suppose you have a bag containing 101 marbles, each inscribed with a number from 0 to 100. If you are a man, you draw one marble from the bag and the number written on the marble you draw will be your “score” (phenotype). If you are a woman, you draw two marbles, and your “score” (phenotype) will be the average of the two numbers written on the two marbles you draw. If you are a man, you are just as likely to draw a large number as to draw a small number; you have an equal probability of drawing any of the 101 numbers, so your “score” can be anywhere on the scale from 0 to 100. In sharp contrast, if you are a woman, your “score” is more likely to be closer to the mean of the scale (50) than to be an extreme value far away from the mean. If you get a very high number – say,

75 – on your first draw, your second draw is statistically likely to be a less extreme value – say, 60 or 40 – than to be an even more extreme value – say, 85 – because, if your first number is very high, then, for your second draw, there are fewer numbers left in the bag that are even higher than your first draw; most numbers still left in the bag are lower than your first draw. The same is true if your first draw is a very low number; you have many more chances to get a higher number on your second draw than to get an even lower number. So, if you are a woman, the average of the two numbers you draw is statistically more likely to be closer to the mean of the scale than the singular number that a man is likely to draw. And this is true of all women and all men; as long as a man's score is a singular value and a woman's score is the average of two values, then women's scores are more likely to be closer to the mean of the scale than men's scores. In other words, the distribution of women's scores will have a *smaller variance* around the mean than the distribution of men's scores. This is why any phenotype that is primarily derived from the X chromosome has a smaller variance among women (who have two X chromosomes, and thus “draw” two values to determine their “score”) than among men (who have one X chromosome, and thus “draw” only one value to determine their “score”). For readers familiar with elementary statistics, this is the manifestation of the Law of Large Numbers at the extreme small end, with $n = 1$ and $n = 2$. Alternatively, one can think of this as a manifestation of the regression to the mean.

General intelligence is a case in point. There is some evidence that genes that affect general intelligence may be located in the X chromosome (Lehrke 1972, 1997; Turner 1996a, b) although more recent studies suggest that other chromosomes might be involved (D'Angelo et al. 2016; Deary et al. 2006; Johnson et al. 2016). Accordingly, studies, reviews, and meta-analyses published during the second half of the twentieth century nearly universally concluded that men and women have identical mean intelligence, but

men have greater variance than women (Ellis 1904; Deary et al. 2003; Eysenck and Kamin 1981; Geary 1998; Herrnstein and Murray 1994; Jensen 1998; Lehrke 1997; Lubinski 2000; Penrose 1963). They used to say “Most geniuses are men; most imbeciles are men,” while most women are near the center of the IQ distribution. The greater variance in intelligence among men than among women is precisely what we would expect if the genes for intelligence are located in the X chromosome.

This universal conclusion from the latter half of the twentieth century, however, has come under increasing attack during the first decades of the twenty-first century. The equality of the mean intelligence between the sexes was partly politically manufactured and achieved partially by the practice by psychometricians of discarding any item on a cognitive test that showed large sex differences (Jackson and Rushton 2006, p. 480). After discarding all test items that showed sex differences, psychometricians naturally achieved the equality of the sexes. There have now been several studies with samples from many nations that show that men may have very slightly (but, in large samples, statistically significantly) higher mean intelligence than women, by about 3–5 IQ points (Irwing and Lynn 2005; Jackson and Rushton 2006; Lynn and Irwing 2004; Nyborg 2005). Some of the confusion and conflict from earlier studies stems from the fact that past researchers have often failed to distinguish between children (boys vs. girls) and adults (men vs. women). Because girls mature earlier than boys, prepubescent girls typically have higher average intelligence than boys of the same age, but the female advantage often reverses after puberty (Lynn 1994, 1999; Lynn and Kanazawa 2011). Some suggest that men have a higher mean intelligence than women, not because they are men but because they are taller – taller individuals regardless of sex tend to have higher intelligence (Jensen and Sinha 1993) – and that, net of height, women are actually very slightly (but, in large samples, statistically significantly) more intelligent than men, by about 1–2 IQ points

(Kanazawa and Reyniers 2009). More importantly for our current purposes, some of these recent studies also show that women have greater variance in intelligence than men do (Irwing and Lynn 2005; Lynn and Irwing 2004). Thus the debate on the sex differences in the mean and variance in intelligence continues.

Polygyny: Sex Difference in Fitness Variance

Another trait that exhibits a large sex difference in variance is reproductive success. Men have much greater *fitness variance* – the difference between the *fitness ceiling* (the best one can potentially do) and the *fitness floor* (the worst one can potentially do) – than women do. The primary cause of the sex difference in fitness variance is the human evolutionary history of mild polygyny.

Clear evidence of our ancestors' polygyny is embodied in each of us: Men are on average taller and heavier than women. Both among primate and nonprimate species, the species-typical degree of polygyny – how polygynous members of a given species are on average – highly correlates with the degree of sexual dimorphism in size (the extent to which males of the species are taller and heavier than females) (Alexander et al. 1979; Leutenegger and Kelly 1977). The more polygynous the species, the greater the size disparity between the sexes. For example, among the completely monogamous gibbons, there is no sexual dimorphism in size; both by height and weight males are about the same size as females. In contrast, among the extremely polygynous gorillas, males are 1.3 times as large by height and twice as large by weight as females (Alexander et al. 1979, pp. 428–430, Table 15–3). On this scale, humans are somewhere in the middle, but closer to the gibbons' end than the gorillas'. Typically, human males are 1.1 times as large by height and 1.2 times as large by weight as human females (Eveleth and Tanner 1976, 1990). This suggests that, throughout evolutionary history, humans have been *mildly* polygynous, not as polygynous as gorillas but not completely monogamous like gibbons either. (For a discussion of *why* the species-typical degree of polygyny correlates with the sexual dimorphism in size, see Miller and Kanazawa 2007, pp. 87–89.)

In a polygynous breeding system, virtually all women reproduce but a large number of men are excluded from reproductive opportunities. Given the roughly 50–50 sex ratio, every man who takes a second wife leaves another man mateless; every man who takes four wives leaves three other men mateless; a king or sultan who maintains a harem of 1,000 concubines leaves 999 men mateless. The more highly polygynous the society, the larger number of men are left out of reproductive opportunities. Under polygyny, reproductive opportunities are roughly equally distributed among women and most women have more or less the same number of children, whereas they are unequally distributed among men and some men have a large number of children while many other men die childless.

The largest number of children that a woman has ever had is 69. The wife of an eighteenth-century Russian peasant, Feodor Vassilyev, had 27 pregnancies in her life, including 16 pairs of twins, seven sets of triplets, and four sets of quadruplets. Amazingly, Mrs. Vassilyeva (her first name is lost to history) never gave birth to a singleton in her entire life! Even more remarkably, all but two of her 69 children survived to adulthood. In contrast, the largest number of children that a man has ever had is *at least* 1,042 (Young 1994, p. 10). The last Sharifian emperor of Morocco, Moulay Ismail the Bloodthirsty, maintained a large harem and had at least 700 sons and 342 daughters. The exact number of children that Moulay Ismail had in his lifetime is not known; the court officials stopped counting daughters after 342, and eventually stopped counting sons after 700, hence the large disparity in the number of sons and daughters. It is true that men of high status are slightly more likely to have sons than other men are (Trivers and Willard 1973) but *not* twice as many. If we assume that Moulay Ismail must have had *roughly* the same number of daughters as sons, then he must have had at least about 1,400 children altogether.

The exact number of children that Moulay Ismail and Mrs. Vassilyeva had is not important. What is important is that the largest number of children that a man can potentially have is *two orders of magnitude greater* than the largest

Sex Differences in Variance Traits,

Fig. 1 Sex differences in fitness variance

number of children that a woman can potentially have (thousands vs. tens), while at the same time many men, but few women, face a great chance of ending their lives as total reproductive losers (leaving no genetic offspring).

Figure 1 presents the theoretical distribution of children that men and women typically have. There are two notable sex differences: The fitness ceiling is much higher for men than for women (men can potentially have a much larger number of offspring), and the fitness floor is much lower for men than for women (the prospect of ending their lives as total reproductive losers is much greater for men than for women). As a result, the fitness variance (the distance between the fitness ceiling and fitness floor) is much greater for men than for women. Men have much greater variability in the number of children they have than women do.

However, while the institution of polygyny creates greater male fitness variance than female fitness variance, other consequences of polygyny can potentially create greater variance among women than among men. Because only some men can reproduce under polygyny while most women do, any sex-linked heritable trait (phenotypes that sons genetically inherit from their fathers and daughters genetically inherit

from their mothers) should exhibit greater variance among women than among men. However, most heritable traits are *not* sex-linked; sons inherit most of their traits equally from their fathers and mothers, and daughters inherit most of their trait equally from their fathers and mothers (Kanazawa and Novak 2005).

Conclusion

While scientists most frequently focus on sex differences in the mean of some trait, sex differences in variance are sometimes of great theoretical and empirical importance. Two primary factors that produce sex differences in variance are genetics and polygyny, both of which typically create greater variance among men than among women. Any phenotype that primarily derives from the X chromosome has greater variance among men than among women because men have only one X chromosome where as women have two X chromosomes, and men have greater fitness variance than women due to polygyny. Sex differences in variability are an often neglected research topic, which can benefit from greater attention in future research.

Definition

Men and women have similar and different mate preferences, which include preferences for type of relationship duration as well as the types of traits that are sought out within each mating duration.

Introduction

Mate preferences include preferences for relationship duration (long-term versus short-term) as well as the types of traits that are sought out in a potential mate within each relationship duration. Men and women are similar on some aspects and different on others. This entry covers some of the key similarities and differences in preferences for both mating context and partner traits within context.

Sex Differences in Relationship Duration Preference

Around the world, both men and women engage in both long-term committed relationships,

including marriage, and short-term sexual relationships, which include casual sexual encounters. There are, however, important sex differences in relationship duration preference such that men, more than women, are likely to prefer casual, short-term sexual relationships; conversely, women, more than men, prefer relationships to be committed and longer term (Buss and Schmitt 1993; Li and Kenrick 2006).

Much of the difference in relationship preference stems from sex differences in minimum obligatory parental investment (Trivers 1972). That is, whereas women are required to invest heavily in offspring because fertilization, gestation, and placentation occur internally and women also carry the additional parental investment associated with lactation after offspring are born, men are physiologically required to contribute only a few sex cells during sexual intercourse to produce offspring. Women's various forms of required physiological investment limit the number of children women can successfully produce; typically the upper bound is about a dozen under optimal conditions, and that upper bound is seldom reached. In contrast, men's minimal constraints enable men to have a much higher reproductive ceiling as the number of offspring a man can have can be increased by pursuing multiple mating opportunities.

Thus, in reproductive terms, the costs of a short-term sexual relationship typically outweigh the benefits for women more so than for men (Li and Kenrick 2006; Symons 1979). Although each individual offspring provides equal reproductive benefits to both parents, they present much higher costs to women if they result from uncommitted sex. Women have therefore evolved to be more selective about potential mates relative to men, as failure to procure the long-term commitment of a mate who provides protection and resources would have been particularly detrimental to survival for impregnated ancestral females, who lived without the benefits of modern food production, public health, medicine (Daly and Wilson 1983), and social welfare. On the other hand, reflecting their rather minimal physiological constraints, men evolved to have greater eagerness for short-term casual relationships and desire

for sexual variety than women (Buss and Schmitt 1993; Kenrick et al. 1990; Symons 1979).

Basic sex differences in sociosexuality (Simpson and Gangestad 1991; Schmitt 2005) reflect these varied preferences between men and women for short- versus long-term relationships. Sociosexuality is a strategic dimension of human mating with a sociosexually restricted orientation associated with lengthier courtships and heavier emotional investments in longer term relationships on one end, and sociosexually unrestricted orientation associated with greater promiscuity, shorter courtship durations, and lesser romantic relationship closeness, on the other end. Individuals who require love and commitment in order to have sexual relations are restricted, whereas those who feel comfortable having sex without love and commitment are unrestricted. Various studies have found that men tend to be more sociosexually unrestricted than women (e.g., Simpson and Gangestad 1991). Schmitt et al. (2001) comprehensive review identifies three areas where sex differences in sociosexuality arise, namely that men possess a greater desire for short-term, casual sexual relationships than women, men prefer larger numbers of sexual partners over time than women, and men require less time before consenting to sex than women. Schmitt's (2005) large study across 48 nations confirmed that sex differences in sociosexuality were generally large, men had higher sociosexuality scores and were thus more sexually unrestricted than women, and these sex differences were cross-culturally universal (although the sex difference appears to be reduced, but not eliminated, by factors such as greater economic gender equality).

Long-Term Mate Preferences

While it has been robustly documented across multiple studies that men are more likely than women to prefer short-term mating (e.g., Buss and Schmitt 1993; Gangestad and Simpson 2000; Kenrick et al. 1990, 1993; Li and Kenrick 2006), humans are also among the few mammals where males develop long-term bonds with their mates and invest in care and nurturance of

offspring (Geary 2005). As humans spend more time in a juvenile state than other mammals, requiring more years of brain and social development before being capable of functioning independently (Björklund and Shackelford 1999), fatherhood as an adaptation carries with it improved fitness of offspring, such as lower child mortality and greater social competitiveness of offspring later in life (e.g., Kaplan et al. 1998). Additionally, human males have relatively higher levels of paternity certainty and lower levels of reproductive success from multiple short-term matings compared to other mammals (Geary 2005), the latter resulting from adaptations in our female ancestors that are both physical (e.g., concealed ovulation; Shackelford et al. 2004) and psychological (e.g., aversion to casual sex and preference for commitment; Schmitt et al. 2001). Therefore, although men can benefit greatly from enacting a short-term mating strategy, various constraints also increase the evolutionary incentive for men to commit to long-term relationships.

When seeking a long-term relationship, the sexes exhibit various similarities – for instance, both men and women are choosy overall when selecting a long-term mate (Kenrick et al. 1990). Humans are like other mammals in that a male's *minimum possible* parental investment is relatively small compared to conspecific females, but different from other mammals in that a male's *typical* parental investment is relatively large compared to males of other mammals. In long-term relationships wherein a male's parental investment and relationship commitment reaches a level comparable to that of females', men become as selective and stringent as women on important partner traits (Kenrick et al. 1990). Buss's (1989) large study on mate preferences across 37 cultures found that the sexes place similarly high importance on traits that include kindness, love, pleasing disposition, and emotional stability in a marriage partner (for a review of universal dimensions of people's mate preferences, see Shackelford et al. 2005).

However, important differences between the sexes also exist. When seeking long-term mates, men value physical attractiveness more than

women do, whereas women value social status and resources more than men do (e.g., Buss 1989). Because women's fertility declines relatively quickly as a function of age, men's reproduction is constrained by access to reproductively valuable or fertile mates (Symons 1979; Trivers 1972). Identifying fertile and healthy mates is thus a primary adaptive problem in both long-term and short-term mating for men. As such, men have evolved a preference for physical features found in young, sexually mature women. Such features, which include firm skin, long and luscious hair, firm breasts and buttocks, and a low waist-to-hip ratio, are predictive of age, health, and fertility (e.g., Buss and Schmitt 1993; Li et al. 2002; Singh 1993), and tend to be preferred by men in both long- and short-term mating contexts.

In contrast to women, men face a much slower decline in fertility across the lifespan, so identifying fertile partners is not as important for women. However, ancestral men varied considerably in their ability to provide resources necessary to the survival of women and their offspring. Thus, women, more than men, evolved to value the ability of a partner in a long-term mating context to provide resources and protection (Buss and Schmitt 1993), which would have been especially important in ancestral times when women were less capable of acquiring resources for or defending themselves and their offspring when burdened with pregnancy and child-rearing. In humans as well as other mammals, social status is an effective proxy for abilities including those to acquire and retain resources. Accordingly, women may have evolved to place a premium on men's social status (Symons 1979) when choosing long-term mates.

There is much empirical support for this evolutionary perspective on long-term mate preferences. Alongside similarities between the sexes on traits such as love and dependability (Shackelford et al. 2005), numerous studies have found that men value physical attractiveness more than women do, and women value social status more than men do. Such studies include experiments that manipulate physical attractiveness and social status in opposite sex target photographs and descriptions and speed-dating contexts (e.g.,

Li et al. 2013), as well as in studies of personal advertisements, consumer behaviors, folk tales, self-concept, self-ideals, and self-esteem, among other contexts.

Short-Term Mate Preferences

Due to the higher reproductive payoffs for men than women when enacting a short-term mating strategy, men have evolved psychological adaptations that facilitate the pursuit of short-term mates. For instance, men are more eager than women to enter short-term relationships (Buss and Schmitt 1993) and report being much more willing than women to engage in sexual relations after any length of acquaintance from one hour up to 5 years. A now-classic study at Florida State University found that when approached by an opposite-sex stranger who immediately made an invitation for casual sex, 75 % of men said "yes," whereas 100 % of women said "no" (Clark and Hatfield 1989). Men are less selective than women when presented with the chance of entering a short-term relationship (Li and Kenrick 2006), which makes it easier and more likely for short-term, casual, and noncommittal sexual relations to occur. Studies have also shown that although both sexes have relatively high minimum requirements for various traits in long-term mates, men but not women significantly lower their standards for casual sexual partners and one-night stands (Kenrick et al. 1990, 1993). Moreover, men may have psychological adaptations designed to minimize commitment after sex (Haselton and Buss 2001). Men who have had more sexual partners (i.e., men who are capable of successfully enacting a short-term mating strategy) are more likely to experience a decrease in how sexually attractive they find their partner immediately following intercourse, whereas neither men with less sexual experience nor women show this decline.

Another source of evidence for men's greater penchant for casual sexual relations or sexual variety comes from studies of homosexual individuals. Gay men, who deal with other men's similar preferences for casual sex (e.g., Symons

1979), tend to have significantly higher numbers of sexual partners than heterosexual men and lesbian women, who have to contend with the commitment-seeking preferences of women. Blumstein and Schwartz's (1983) large study on American couples found that only 36 % of gay men stated that it was important to them to have a sexually monogamous relationship, compared to 71 % of lesbians, 75 % of heterosexual men, and 84 % of heterosexual women. When actual sexual behavior was examined, only a minority of lesbians (28 %), heterosexual men (26 %), and heterosexual women (21 %) had engaged in sex outside their primary relationship, while majority of gay men (82 %) engaged in sexual intercourse outside their primary relationship. The authors also reported a positive correlation between sexual fidelity and relationship satisfaction that applied to lesbian and heterosexual couples but not for gay male couples. Gay men in relationships are therefore more likely to have shared sexual preferences that allow for agreements permitting casual sex outside their primary relationship.

Despite this well-documented sex difference in relationship duration preference, many women also engage in short-term mating. Given that each act of heterosexual sex involves a man and a woman, the average number of sexual partners for men and women who engage in short-term mating should be identical (Greiling and Buss 2000). Additionally, if women in ancestral times had never engaged in short-term mating, men could not have evolved the desire for sexual variety. Therefore, regardless of preferences for a longer versus shorter relationship duration, women often engage in short-term mating and have likely evolved to value specific traits in a short-term mate that differ from those they seek in a long-term mate.

A relationship that is primarily sexual and uncommitted makes obtaining a continuous flow of resources much less important, if not irrelevant (Li and Kenrick 2006). Thus, women likely did not evolve a strong preference for resources in a short-term mating context. Instead, women may have evolved to value the quality of a short-term partner's genes, which can be conferred to

offspring (Buss and Schmitt 1993; Gangestad and Simpson 2000). Specifically, women may have evolved to be physically attracted to short-term mates displaying visible markers of good quality genes. Such markers may include the presence of both masculinity and symmetry, which indicates that despite having abundant testosterone (which increases masculine features but also suppresses the immune system), a male has effectively resisted pathogens that can cause asymmetrical development. Consistent with this reasoning, studies have shown that women find symmetry and masculinity to be desirable when considering a short-term mate and when ovulating (Gangestad and Simpson 2000; Gangestad and Thornhill 1997). Women also value size, muscularity, and physical strength in their short-term mates (Frederick and Haselton 2007; Li and Kenrick 2006), which may help them obtain physical protection (Smith 1984).

Women's fertility is especially important for a short-term context, where other considerations, such as the coordination of parenting, are less or not relevant. As such, men likely evolved to value physical attractiveness across both long- and short-term mating contexts (Buss and Schmitt 1993). Indeed, both sexes have been found to value and prioritize physical attractiveness above other traits in short-term mates (Kenrick et al. 1990; Li and Kenrick 2006), with men valuing and prioritizing physical attractiveness even more in a short-term mate than in a long-term mate (Kenrick et al. 1990; Li and Kenrick 2006). So, both sexes highly value physical attractiveness when considering short-term mates, though for different underlying adaptive reasons.

Criticisms and Responses to Criticisms of Evolutionary Perspectives on Mate Preferences

Recently, various criticisms have been levelled at evolutionary theories of sex differences in mate preferences. First, as raised by Li et al. (2002), preferences for physical attractiveness and social status do not seem to be rated or ranked highly enough in empirical studies to warrant the critical

importance espoused by evolutionary theory. For example, physical attractiveness was ranked sixth out of 13 in importance by men and good earning capacity was ranked tenth in importance by women (fairly low rankings for supposedly important traits; Buss and Barnes 1986). Second, as raised by Eastwick and Finkel (2008), various studies conducted in live interaction settings failed to find these sex differences (e.g., both sexes appeared to equally value physical attractiveness) as well as links between people's stated mate preferences and the criteria they use in selecting actual mates. However, these concerns were addressed by theories and findings guided by the *mate preference priority* model (Li et al. 2002, 2013; Li and Kenrick 2006; Li and Meltzer 2015).

According to this model, although numerous traits are valued in a mate, such as kindness and creativity, many of these traits are "luxuries" compared to traits that are more critically vital to reproductive value, such as physical attractiveness for men and social status for women. These traits are evolutionary "necessities" in mating – traits that must be present at some minimum level of requirement in a potential mate in order for reproduction to be successful. Accordingly, it is adaptive for individuals to reject potential mates with low levels of necessity traits – those who, in ancestral times, would not have been able to reproduce or contribute to the survival of offspring – at initial stages of mate selection to minimize the costs of poor mate choice later on. Thus, despite having similar preferences for an ideal well-rounded mate, men and women likely have evolved mechanisms that first prioritize different necessity traits in long-term partners before other luxury traits (Li et al. 2002).

Specifically, men may have evolved to first seek mates who pass a minimum threshold on physical attractiveness, whereas women may first seek mates who pass a minimum threshold on social status. After acceptable levels of these necessity traits have been acquired or verified, other luxury traits – which also contribute to reproductive fitness – are then considered and become more highly valued. Direct support for the mate preference priority model comes from studies using a budget allocation methodology as

well as a mate screening paradigm, which have shown that sex differentiation in mate preferences occurs in the predicted directions when choices are made between low levels of necessity traits during the initial stages of selection for long-term mates (Li 2007; Li et al. 2002, 2011; Li and Kenrick 2006). Moreover, Li and colleagues (2013) experimentally tested this paradigm by manipulating the physical attractiveness and social status of chat partners in a live, speed-dating context. This work addressed a key limitation of previous live interaction studies in which participants representing the low end of necessity traits such as social status may have been absent, hence undermining the relevance of those traits to mate selection. Indeed, when physical attractiveness and social status were manipulated such that individuals at the low end of these traits were present, the predicted sex differences then emerged as men declined potential mates low in physical attractiveness while women shunned those who were low on social status. When mating duration was clearly specified, these sex differences were pronounced for long-term but not for short-term relationships. For short-term relationships, both sexes avoided partners with low physical attractiveness.

Compromises in Mate Preferences

Given that the sexes ideally desire different types of relationships, compromises need to occur in order for mating to actually occur, thereby leading mating strategies to converge and reflect a greater degree of similarity than what each sex ideally prefers. For instance, many men likely have to compromise on their preference for short-term casual relationships in order to attract women, who tend to have a strong preference for long-term committed relationships. Similarly, women may have to yield on some of their desired commitment due to men's ideal preference to not provide it. Compromise and convergence of mating strategies and preferences are by-products of each sex pursuing different strategies and imposing mutual constraints, though the ability for mating strategies and preferences to adjust to such

constraints needs to have evolved in order for the flexibility to occur. Below, several lines of research that illustrate such compromises are described.

Firstly, mating strategies have been shown to be facultatively responsive to the adult sex ratio of the local ecology (i.e., ratio of men to women in a population; Schmitt 2005). In environments where high-quality men are a scarce and valuable commodity (e.g., places plagued by war), these desirable men can demand short-term mating and obtain it, as it may be in a woman's best reproductive interests in these circumstances to agree to short-term mating than risk not reproducing at all. Conversely, in female-scarce environments (e.g., China, where a combination of favoring male offspring and the one-child policy has created a large male-to-female sex ratio), relationships tend to be longer term and monogamous. As women are highly sought after and have high value in female-scarce mating markets, it makes greater reproductive sense for a man who is fortunate enough to attract a mate to focus on keeping her (by fulfilling her ideal desires) rather than losing her to the next guy who does, or by futilely seeking additional mates.

Secondly, as mentioned above, homosexual relationships can be meaningfully compared to heterosexual relationships to gain insights into mating psychology. In homosexual relationships, individuals are unencumbered by the different preferences of the opposite sex; thus, there is less need to compromise on dimensions where the sexes differ. So, whereas heterosexual men have to contend with and compromise due to women's preference for committed, long-relationships, homosexual men, whose partners are other men, do not face this constraint. Similarly, lesbian women deal with the mostly long-term preferences of other women rather than the largely short-term, sexual preferences of men. Indeed, reflecting these differences, studies have found that lesbian relationships tend to be committed and longer term, while gay men engage in casual short-term relationships more frequently than heterosexual men (Symons 1979).

Third, while much research on human mating relationships has focused on long-term relationships (e.g., cohabitation, marriage) and short-term relationships (e.g., one-night stands, hook-ups) as two polar-opposite and competing relationship

types, other evidence suggests that the range of potential relationships extends beyond this relationship dichotomy and can include other arrangements such as "friends with benefits" and "booty-calls" (e.g., Jonason et al. 2009). These alternative arrangements emerge as compromise relationships resulting from men and women pursuing their different, preferred mating strategies. Booty calls tend to utilize various communication mediums to facilitate sexual contact among friends who, for men, may represent low-investment, attractive sexual partners and, for women, may represent attractive test-mates and long-term possibilities (Jonason et al. 2009). Such relationships serve as a compromise between men's and women's ideal mating strategies that allows men greater sexual access and women an ongoing opportunity to evaluate and obtain potential long-term mates.

Finally, assortative mating, where individuals of similar "mate value" tend to partner up, also occurs as a result of people's ability to compromise in competitive mating markets. An individual's overall mate or reproductive value can be defined as the sum of his or her traits (e.g., Kirsner et al. 2003). In a competitive mating market, a person's reproductive value should be reflected by their overall desirability to the opposite sex. While self-reported preferences predict that people find high mate value individuals attractive and would prefer to mate with them, the constraints of the mating market typically create gaps between ideal mate preferences and actual choices, especially for exclusive long-term relationships. For example, most women might prefer a generous husband with a high income and lavish lifestyle (Buss and Barnes 1986), but not all women can actually obtain such a husband. People are therefore expected to mate based on what positive qualities (i.e., mate value) they possess relative to a prospective partner's mate value in an assortative manner (Kenrick et al. 1993). Pursuing partners with a significantly different mate value is likely to be costly; for instance, it is difficult to attract as well as retain a mate whose mate value is higher than oneself, while acquiring a partner whose mate value is too low may lead to relationship dissatisfaction and wasted mate value. Therefore, the constraints of the mating market drive

individuals to adjust their standards in a partner such that they are eventually assortatively mated based on their perceived mate value. Studies have indeed demonstrated that individuals' mate preferences are indexed to their self-perceived value on the same traits (Kenrick et al. 1993) and couples tend to comprise of individuals of similar mate value (e.g., Figueredo et al. 2006).

Conclusion

This entry has described how men's and women's mate preferences, which include preferences for both mating context and traits within a context, are both different as well as similar. The sex differences are robust across time and culture and have likely evolved due to key differences in minimum obligatory parental investment as well as differences in fertility across the lifespan. Likewise, the considerable overlap that men and women share in their preferences also likely reflect evolved preferences, such as both sexes' preference for physical attractiveness in a short-term mating context (though for different underlying reasons), as well as processes of convergence due to both sides needing to compromise, such as when men and women adapt their relationship strategy to the other side's demands or when individuals mate assortatively. Together, these similarities and differences reflect a wide range of human mating behaviors.

Definition

Adolescent girls' and women's penchant for indirect aggression has led to the prediction that gossip may be their preferred tactic of choice when competing against intrasexual rivals. Consequently, girls and women are predicted to initiate and engage in gossip more frequently than boys and men.

Introduction

Gossip has been defined as a form of evaluative communication that permits individuals to exchange positive and negative information about absent third party others (Leaper and Holliday 1995; Levin and Arluke 1985). It is a construct that overlaps conceptually with rumor, but is distinct in that it tends to be truthful and about people as opposed to events (Foster 2004). The historic and cross-cultural ubiquity of gossip, as well as the consensus among researchers that it plays a vital role in human social relationships, has led to the proposal that it may be an evolved psychological adaptation that enabled our ancestors to survive and reproduce (Barkow 1992; Dunbar 2004; McAndrew and Milenkovic 2002; McAndrew et al. 2007). This evolutionary perspective challenges the notion that gossip constitutes idle "chitchat" and the mere passing along of trivial everyday details for the purpose of enjoyment. It also helps to contradict the pejorative gender stereotype sometimes associated with women's gossip by demonstrating that men also gossip to a significant extent. From this view, gossiping plays an essential role in how both sexes relate to and choose to coexist with other human beings (Foster 2004; McAndrew 2014); perhaps even to the point of defining the social group itself.

Gossip as an Adaptation to Overcome Adaptive Problems

As an adaptation, gossip is posited to be a heritable trait that was selected for because it helped to

solve problems linked to survival (e.g., locating food) and/or reproduction (e.g., gaining access to potential mates; see Davis et al. 2018 and McAndrew 2014 for discussion). Gossip has likely been preserved and has proliferated throughout human populations over time because it ultimately enhanced the reproductive success of our ancestors in the environment within which it was selected. What adaptive problem(s) might gossip have solved? For Dunbar (2004), the key adaptive challenges that gossip helped to overcome were those linked to group living.

In comparison to other primates, humans are unparalleled in their capacity for, and reliance upon, cooperation, cultural transmission, conformity, coalitional alliances, and "group-mindedness" (Barkow 1992; Dunbar 2004). To function in highly expansive communities requires an efficient means of gathering, sharing, and vetting information about others, as well as ways of encouraging cooperation and minimizing rule breaking (Foster 2004). Dunbar (2004) proposed that gossip helped to meet these challenges by (1) keeping track of others embedded in complex social networks, (2) emphasizing one's potential as an ally, friend, or mate, (3) soliciting help from others regarding personal dilemmas, and (4) policing the duplicitous and exploitative actions of others. Similarly, Barkow (1992) argued that social living necessitates tracking the actions of peers and developing the capacity to predict and influence the behavior of others in order to vie for finite resources linked to fitness. To this end, gossip may be instrumental for our success in social competition as a tactic for reputation management and to facilitate the creation of internal representations of others who are likely to impact our fitness such as kin, allies, mates, and rivals (Barkow 1992; McAndrew et al. 2007).

Over evolutionary time, women and men have faced many of the same adaptive hurdles, such as detecting the presence of dangerous predators and competing for potential mates. However, it is evident that the favored competitive strategies, reputational concerns, mating interests, as well as the character of kin networks and alliances differ substantially by sex (Barkow 1992; Campbell 1999, 2004; Vaillancourt 2013). This is the case because

women and men have recurrently faced many different adaptive problems over their evolutionary histories, which has led to the selection of divergent adaptations with sex-specific design features (Arnocky 2016; Arnocky and Vaillancourt 2017; Buss 1989). The domains within which women and men have faced different adaptive problems are defined by the process of sexual selection, whereby traits like gossip are selected because they provide a reproductive advantage (Arnocky 2016; Buss and Dedden 1990). Sex can be defined as consistent, but flexible, variation in reproductive anatomy and function, hormone levels, and chromosomal makeup (Davis et al. 2018). Sex is distinct from, but inseparably interrelated with gender, which tends to be defined as the attitudes and behavior that a particular culture associates with sex.

Adaptations that emerge through the process of sexual selection manifest as a consequence of choosing preferred mates (i.e., intersexual selection) and through competition with members of the same-sex for access to opposite-sex mates (i.e., intrasexual competition; see Davis et al. 2018 for discussion). In the realms of social and mating competition, our primary rivals tend to be same-sex others because they have faced the same adaptive problems and thus seek the same resources to meet these evolutionary challenges (Barkow 1992; Buss 1989). Importantly, sexual selection embodies competition for mates and resources that influence the probability of mating, such as popularity and status (Arnocky 2016). Intrasexual competition among humans involves diverse tactics including, but not limited to, emphasizing one's desirable qualities as a mate (i.e., self-promotion) and manipulating the reputations of competitors to lower their desirability as a mate relative to ourselves and diminish their capacity to compete (i.e., competitor derogation; Buss and Dedden 1990; Campbell 2004).

Gossip as an Intrasexual Competition Strategy

Evidence supports the argument that gossip is a key tactic for intrasexual rivalry. Davis et al.

(2018) found positive relations between self-reported intrasexual competitiveness, a tendency to gossip, and positive attitudes toward gossiping for both women and men. Furthermore, researchers have confirmed that we are most interested in, and share more negative gossip about, same-sex others of a similar age who are our primary intrasexual competitors in the context of heterosexual mating (McAndrew et al. 2007; McAndrew and Milenkovic 2002; McDonald et al. 2007; Owens et al. 2000). In the domain of mate competition, malicious gossip and rumor may be used to derogate rivals in an effort to lower their mate value and to access and retain reproductive resources (Arnocky and Vaillancourt 2012; Buss and Dedden 1990; Campbell 2004). This negative gossip is described as a type of indirect aggression which refers to a range of covert acts intended to influence and exploit interpersonal relationships, including social exclusion, spreading harmful gossip and rumors, and breaking confidences (Vaillancourt 2005, 2013).

Spiteful gossip, like other types of indirect aggression, is an effective mate competition tactic because it can be damaging to its targets (e.g., lowering self-esteem and increasing risk of depression for victims; see Vaillancourt 2013 for review) and it can be used to elevate our social standing (Vaillancourt and Hymel 2006), providing greater access to reproductive opportunities (Arnocky 2016; Arnocky and Vaillancourt 2012). Furthermore, gossip can be employed to manipulate social information in our favor and to impugn the reputation of rivals while disguising the identity of the gossiper, which reduces the probability of physical, verbal, or social retaliation (Arnocky 2016; Arnocky and Vaillancourt 2017; Vaillancourt 2013). Nonetheless, many social norms govern gossiping, which if violated can result in reputational damage and social exclusion (Foster 2004). Therefore, spreading and listening to malicious gossip carries a certain level of risk, despite its stealthy nature. Cross-culturally, adolescent girls and women have been shown to prefer more covert and circuitous modes of aggression such as negative gossip and social exclusion, whereas boys and men are more likely to engage in risky and direct forms of aggression

(e.g., verbal taunting and physically hitting another; Benenson et al. 2013; Björkqvist 1994; Campbell 1999, 2004; Owens et al. 2000; Vaillancourt 2005, 2013; Vaillancourt et al. 2010). This sex difference in the proportional use of different types of aggression corresponds to the unique adaptive challenges faced by ancestral women and men.

Despite being a species that engages in biparental care, women's higher degree of obligatory parental investment, through gestation, child bearing, and post-partum care, and their smaller number of gametes translates into a lower lifetime reproductive potential in comparison to men (Arnocky and Vaillancourt 2017; Campbell 1999, 2004). In contrast, men's reproductive output is largely constrained by their capacity to outcompete same-sex rivals to obtain reproductive opportunities. A mother's death has also been found to increase the risk of child mortality more than a father's death, underscoring the importance of maternal investment. Ancestral women, therefore, could less afford to engage in risky and violent forms of intrasexual competition and benefited by carefully selecting successfully competitive mates who were able and willing to invest (Arnocky 2016; Campbell 1999, 2004; Vaillancourt 2013). The larger cost associated with women's use of risky and directly aggressive mate competition tactics can be seen in their preference for indirect aggression and their relative absence of armament designed for direct intrasexual combat (e.g., smaller stature, less muscle mass) in comparison to men. Girls and women, relative to boys and men, are therefore predicted to use gossip as a mode of indirect aggression to compete against intrasexual rivals for mates and to establish and maintain status within their peer groups (Eckert 1990; Leaper and Holliday 1995; McDonald et al. 2007; McAndrew 2014; Vaillancourt 2005, 2013). This proclivity may correspond to a greater tendency to gossip, greater enjoyment of the activity, and a stronger inclination to gossip for intrasexually competitive purposes. For the same reasons, girls and women may be more likely to initiate the spreading of gossip than boys and men.

Several studies have supported the hypothesis that girls and women tend to gossip more than boys and men (Björkqvist et al. 1992; Davis et al. 2017; Leaper and Holliday 1995; Levin and Arluke 1985). There are also sex differences with whom men and women gossip. McAndrew et al. (2007) found that women were just as likely to share gossip with a same-sex friend as with their romantic partner, whereas men were significantly more likely to share gossip with their mates than with anyone else. Furthermore, women have been shown to express a stronger desire to hear gossip about members of their own sex and are more likely to gossip about same-sex friends and relatives in comparison to men (Leaper and Holliday 1995; Levin and Arluke 1985; McAndrew and Milenkovic 2002). Björkqvist et al. (1992) demonstrated that adolescent girls were nominated by their peers to be significantly more likely to spread malicious gossip in comparison to boys. Low et al. (2010) found that preadolescent and adolescent girls transmitted more malevolent gossip than boys and were more likely to be the targets of negative gossip. Women and men appear to spread a similar proportion of negative and positive gossip about other people in general (Levin and Arluke 1985); however, higher rates of spiteful gossip have been found to occur in female friend groups in comparison to male friend and female-male friend groups (Leaper and Holliday 1995). These findings support the idea that girls and women initiate gossip more than boys and men, particularly when spreading derogatory gossip about familiar others to same-sex peers.

Sex Differences in Initiating Gossip Episodes

To our knowledge, only one study has directly examined differences between women and men in who is more likely to be the first person to spread real or fake information about someone among mixed-sex groups. Levin and Arluke (1985) found that female friends initiated more negative gossip than male friends and cross-sex friends. Male friends were less likely to initiate the

spread of positive gossip; however, cross-sex friends were just as likely as women to initiate favorable gossip. Further investigation of sex differences in the initiation of gossip is needed to examine if women are more likely to start an episode of gossip in comparison to men within cross-sex groups. Women may be more likely than men to initiate gossip, particularly of a negative valence, with opposite-sex others because of their greater tendency to gossip among same-sex friends and their preference for using gossip as an indirect mode of aggression to compete against intrasexual rivals (Campbell 1999, 2004; Davis et al. 2018; McAndrew 2014). Nonetheless, a range of developmental, individual difference, interpersonal, and contextual factors are expected to influence this predicted sex difference.

Adolescent girls and young women are predicted to compete more intensely for mates and things linked to fitness (e.g., status, popularity) than younger girls and older women because of their relatively greater reproductive capacity and mate value (Campbell 1999, 2004; Massar et al. 2012; Vaillancourt 2013). Low et al. (2010) found that girls in grade six (aged 11–12) were more likely to gossip and to be the targets of gossip than girls in grade three (aged 8–9). Similarly, Björkqvist et al. (1992) found that 15-year-old girls were peer-nominated to be significantly more likely to spread negative gossip than their 8-year-old counterparts. Massar et al. (2012) demonstrated that young adult women reported gossiping more than their older same-sex peers. The authors found that this relation was mediated by mate value, such that more physically attractive women gossiped more often than their less attractive counterparts (Massar et al. 2012). Therefore, physically attractive adolescent girls and young women are more likely to initiate gossip about same-sex others because of their greater tendency to engage in the activity and their greater susceptibility to being the targets of gossip.

In comparison to boys and men, girls and women should be particularly likely to initiate gossip when it is being used to attack the relationships of same-sex peers. This is because girls and women regard close intimate friendships as more important than do boys and men and have tighter

social structures (Eckert 1990; McDonald et al. 2007). Researchers have supported that girls and women are more likely to be the targets of indirect peer victimization, such as malicious gossip, and are more susceptible to the psychological harm caused by this behavior (e.g., increased risk of depression, suicidal ideation; Benenson et al. 2013; Owens et al. 2000; see also Vaillancourt 2013 for discussion). At the same time, gossip can be a powerful social bonding mechanism that enhances intimacy and solidarity (Eckert 1990). This is likely of greater importance to girls and women who prefer close dyadic relationships characterized by intimacy, security, closeness, and trustworthiness (McDonald et al. 2007). Among older adolescent girls, qualitative reports have confirmed that aggressive gossip can play an important role in developing close personal relationships and peer acceptance (Owens et al. 2000). Perhaps girls and women initiate gossip more than boys and men when seeking to damage the relationships of same-sex others via indirect aggression and initiate the spread of negative gossip about others more often to enhance intimacy and acceptance among the peer group.

Because girls and women appear to place more value on their intimate same-sex friendships, are more relationally aggressive, and are more susceptible to the damage wrought by relational victimization relative to boys and men (see Eckert 1990 and Vaillancourt 2005, 2013 for discussion), it is sensible to predict that they may gossip more about social information (Davis et al. 2018). This would presumably allow girls and women to acquire vital knowledge about people in their social circles, to derogate intrasexual rivals, and to protect their relationships and themselves. In previous work, girls and women have been shown to gossip more about peers, friends, family members, the dating and romantic relationships of others, and to read gossip more often in the media (Davis et al. 2018; Eckert 1990; McDonald et al. 2007). Women have also been found to perceive more value in gossiping and to find the activity more enjoyable than men (Davis et al. 2018). Girls and women may then be more likely to initiate gossip when it concerns social information because these details are argued to be more

pertinent to their intrasexual competition than amongst boys and men.

Along with social information, several sex differences in the initiation of gossip likely vary across different content domains where women and men have encountered divergent adaptive problems (Buss and Dedden 1990). The mate preferences of one sex become the traits over which the opposite sex competes (Arnocky 2016; Arnocky and Vaillancourt 2017). Women's greater obligatory parental investment, the importance of maternal investment for the survival of offspring, and the fact that humans have more altricial young translates into women facing the adaptive challenge of securing mates who are both able and willing to invest significant resources in them and their offspring and to offer protection. Therefore, men are predicted to compete with one another to display and to derogate each other on traits linked to resource acquisition and holding potential such as status, achievement, ambition, and industry, as well as their physical strength and stature (Buss and Dedden 1990).

Davis et al. (2018) found that men gossiped more about achievement-related content in comparison to women, such as the salaries and work successes of others. Similarly, people also spontaneously recall gossip about the status and wealth linked to a hypothetical man more often than a similar fictional woman (De Backer et al. 2007). However, Levin and Arluke (1985) found that women were more inclined than men to gossip about schoolwork, such as teacher evaluations, exams and papers, and other students' grades. Men's frequent gossip about televised sports has been noted by previous researchers (e.g., Johnson and Finlay 1997). Unsurprisingly, adolescent boys and men have been found to gossip more about athletic performance and sports figures (Levin and Arluke 1985). These results suggest that the content of boys' and men's gossip generally corresponds to the evolved mate preferences of girls and women. Therefore, boys and men are predicted to initiate gossip about achievement and athletics more often than girls and women.

Due to men's paternity uncertainty, higher reproductive potential, cheap and replenishing gametes, as well as the inconspicuous nature of

women's ovulation, ancestral men faced the adaptive challenge of finding, courting, and securing fertile and sexually faithful mates (see Arnocky 2016 and Arnocky and Vaillancourt 2017 for discussion). Consequently, men have evolved to prefer women displaying cues linked to health, reproductive value, and fertility (e.g., youth, facial femininity, unblemished skin, full lips, large breasts, and a low waist-to-hip ratio), as well as sexual fidelity (Buss 1989). Therefore, women are predicted to compete primarily with same-sex rivals over traits like youthfulness, physical appearance, and sexual reputation.

Girls and women, more than boys and men, have been shown to derogate each other on their appearance using terms such as "ugly" and "fat" (Buss and Dedden 1990; Campbell 2004; Vaillancourt 2013). Key drivers for adolescent girls' malicious gossip and social exclusion are envy over the appearance of same-sex others and jealousy over preferred male mates (Owens et al. 2000). Women have also been found to report greater feelings of jealousy and competitiveness when exposed to images of attractive women or when they perceive other women as being more physically attractive than they are (Arnocky et al. 2012). Similarly, women have been found to gossip more about the physical appearance of others (Davis et al. 2018). In addition, women and men have better spontaneous recall for gossip about the attractiveness of a fictional woman relative to a fictional man (De Backer et al. 2007). These results support the hypothesis that girls and women are more likely to initiate gossip about the physical appearance of others, particularly when the gossip is targeting a same-sex rival.

The most common insults that women direct toward same-sex rivals concern their sexual faithfulness and drawing attention to, or exaggerating, their promiscuity (Buss and Dedden 1990). Pejorative terms like "slut," "whore," and "ho" are common in the gossip and rumors of women's competitor derogation (Vaillancourt and Sharma 2011; see Campbell 2004; Vaillancourt 2013). Although rare among women, the most commonly reported reason for women's physical violence is retaliation in response to allegations of being licentious (see Campbell 1999).

Vaillancourt and Sharma (2011) demonstrated experimentally that women voluntarily derogated a promiscuously dressed female research confederate more than the same woman dressed in more conservative clothes. These results indicate that women compete against same-sex others and often maliciously manipulate the sexual reputation of their victims using gossip. Therefore, adolescent girls and women may initiate more derogatory gossip about a same-sex rival's sexual reputation in comparison to boys and men.

Conclusion

Gossip plays an important role in the social dynamics and interpersonal relations of human beings (Dunbar 2004; Foster 2004). It is likely an adaptation that was sexually selected because it provided a reproductive advantage to ancestral human beings. Gossip may have evolved to solve adaptive problems in several domains that differentially impinged on the survival and reproduction of ancestral women and men. Thus, several authors have predicted that gossip has sex-specific design features (Campbell 1999, 2004; Davis et al. 2018; McAndrew 2014; Vaillancourt 2013). Evidence to date supports the hypothesis that girls and women initiate gossip more than boys and men, particularly when gossip is negative and shared among same-sex friends. It is somewhat unclear, however, whether women initiate more gossip episodes than men within mixed-sex groups. Due to their greater tendency to gossip and to use gossip to gather valuable social information as well as to derogate rivals, girls and women likely initiate gossip more often than boys and men in cross-sex groups. This propensity may be stronger for attractive adolescent girls and women, particularly during their earlier reproductive years when mate competition intensifies (Massar et al. 2012; Vaillancourt 2013) and when the content relates to a rivals physical appearance and sexual reputation. In contrast, boys and men may initiate gossip more often when it concerns content related to women's evolved mate preferences, including cues to resource holding potential and physical formidability.

Definition

The process of gathering accurate information, developing attitudes and beliefs, and gaining skills on the biological, sociological, and psychological facets of sexuality in a formal academic setting.

Introduction

Sexuality education provides individuals with information about their bodies, identities, relationships, and health-promoting skills as they relate to sexuality. International health and human rights organizations assert that access to developmentally and culturally appropriate sexuality education is a basic human right (UNESCO 2018). Adolescents receive sex education from formal sources, like schools or clinics, and informal sources, like family members, friends, or digital resources. While these can all be important, affirming sources of information, formal sources are more likely to provide students with accurate and age-appropriate information (UNESCO 2018). Formal sex education is most commonly implemented within a school setting, which has

the potential to provide additional benefits to the students. Schools are already equipped to provide education and, ideally, foster a supportive learning environment. Additionally, schools are often already connected with other community resources and can reach out for support, information, or special needs as needed (UNESCO 2018). Developmentally appropriate sex education can be offered to students of any age within schools; however, research has overwhelmingly focused on youth between the ages of approximately 9 and 18. Similarly, this entry will focus on the impacts of sex education in schools that is delivered to students ages 9–18.

While the goals of sex education in schools have historically focused on improving health outcomes, these goals have been expanded as sex education programs increasingly adopts a human rights framework (Haberland and Rogow 2015; UNESCO 2018). The quality of sex education programs can be assessed with a wide variety of metrics. At the individual level, the ideal sex education program would increase knowledge on delivered topics, help students understand their identity and culture, and promote the development of health-promoting skills (Haberland and Rogow 2015; Kirby 2008; Kohler et al. 2008; UNESCO 2018). As a result of targeting student knowledge, attitudes, and beliefs, an ideal program would also improve students' biological, psychological, and social health outcomes. These outcomes may include STI (sexually transmitted infection) status, unintended pregnancy, or experiences with intimate partner violence. A program's effectiveness may also be evaluated at the social level, measuring a programs effect on issues like community-wide health outcomes, gender equity, discrimination, etc. (Haberland and Rogow 2015; UNESCO 2018).

Sexuality education programs vary in their ability to impact health. The most successful programs employ a holistic view of sexuality, empower their students, are inclusive of students with different identities and experiences, and explicitly discuss structural and cultural issues (UNESCO 2018). Moving forward, educators, policy makers, and researchers across the globe are advocating for more programs that feature

these qualities. Additionally, sex educators are exploring ways to build new, interdisciplinary organizational partnerships and to integrate new technology into their programs to create programs that have a greater impact and reach.

This entry will focus on comprehensive sexuality education programs and exclude abstinence-only and abstinence-plus programming. Comprehensive sexuality education programs provide students with age-appropriate, accurate, and inclusive information on biological, psychological, and sociological aspects of sexuality (UNESCO 2018; WHO Regional Offices for Europe and BZgA 2010). In contrast, abstinence-focused programs are designed to encourage adolescents to delay sexual activity, often until marriage, and highlight the risks related to sexual activity (Santelli et al. 2017; Underhill et al. 2008). While these programs are often labeled as sex education, they often feature misinformation, exclude LGBTQ+ students, and limit the information available to students about their bodies and identities (Santelli et al. 2017). As abstinence-focused programs are not designed to provide accurate, inclusive, and developmentally appropriate information on the biological, psychological, and sociological facets of sex, they do not fit within the definition of sex education.

The Need for Sex Education in Schools

Developmentally appropriate sex education can provide valuable information to individuals of all ages, but is of particular value to adolescents. Adolescence marks the time when an individual is transitioning, physically and socially, from a child to an adult. This transition is often marked by changes to an individual's body, identity, relationships, and social role. Providing sex education in schools can help foster a more supportive and safer environment for adolescents as they process not only their own transition, but the transition of their peers. Additionally, it provides students with valuable experience discussing topics related to sexuality with their peers. The communication skills developed during these discussions can

then later be applied to conversations they have with partners, friends, family members, and healthcare providers.

Goals of Sex Education

As the contents of sex education programs have expanded beyond the individual to provide students with information on interpersonal and social factors that may influence a broad understanding of sexuality, so have the goals of the program expanded. These goals are then translated into metrics by researchers to evaluate the effectiveness of sex education programs. The following are common goals of sex education programs (Haberland and Rogow 2015; Hirst 2012; UNESCO 2018):

Improved safer sex behaviors. This includes behaviors such as condom use, contraceptive use, or seeking medical care as needed. Sex education programs often promote safer sex behaviors by providing information on the benefits of these behaviors and practicing skill building, like putting a condom on a model. Some programs even go one step further and teach students how to communicate with partners about safer sex behaviors and how social ideas about gender and power may influence and impact safer sex behaviors.

Reduce STI rates. Programs often work to reduce STI rates by promoting safer sex behaviors that can prevent STI transmission, along with providing information on testing and treatment. The information provided to students on STI transmission has evolved in response to changes in available medical care and the infections themselves. Reduction in HIV transmission, specifically, has been a primary goal of sex education programs globally since the 1980s.

Improve adolescent reproductive health. This goal may include a reduction in unintended adolescent pregnancies and births, improved access to contraceptives, and improved access to safe medical services, such as abortions. Similar to the method for reducing STI transmission, programs often target adolescent reproductive health by improving safer sex behaviors and providing

information on how to access appropriate resources.

Age of first penile-vaginal intercourse and number of partners. Many sex education programs seek to increase the age of first penile-vaginal intercourse and reduce the number of partners. Though these measures are correlated with health behaviors and outcomes, this relationship appears to be heavily affected by mediating variables (Sandfort et al. 2008). For example, research suggests that individuals who are younger at the age of first penile-vaginal intercourse, as compared to their peers, are more likely to report engaging in risky sexual behaviors and have an STI (Cavazos-Rehg et al. 2010; Ma et al. 2009; Magnusson et al. 2012; Sandfort et al. 2008). However, age of sexual intercourse, STI rates, and safer sex behaviors also correlate with gender, ethnicity, culture, family systems, mental health, and drug and alcohol use, among others (Cavazos-Rehg et al. 2010; Sandfort et al. 2008; Udell et al. 2010). Additionally, the way researchers address the variables of age at first intercourse, and number of partners varies greatly with differences in researchers' cultures and societal attitudes toward adolescent sexuality (Sandfort et al. 2008; Udell et al. 2010). Programs achieving their goal of increasing age at first intercourse and reducing the number of sexual partners an individual have may improve health, but the mechanics of this pathway are still unclear.

Reduce intimate partner violence, gender-based violence, violence against LGBTQ+ individuals, and discrimination. Violence and discrimination related to sexuality exists internationally at interpersonal and cultural levels (Gay et al. 2010; Haberland and Rogow 2015; UN Human Rights Council 2015; UNESCO 2018). In the twenty-first century, innovative programs have worked to reduce violence and discrimination by teaching about both the behaviors and the cultural context in which they exist. This information can empower students to reflect on social norms, their own behavior, and the behavior of others. Research suggests that programs designed to target these issues not only reduce violence and discrimination, but they also appear to have a greater positive impact on engagement in safer

sex behaviors, STI rates, and reproductive health outcomes than programs that do not address relational violence and discrimination (Haberland and Rogow 2015; UNESCO 2018).

Reduce health inequities. Members of vulnerable populations, including LGBTQ+ individuals, individuals with disabilities, those who have experienced intimate partner violence, those who have experienced homelessness, and refugees, often experience the worst sexual health outcomes (Haberland and Rogow 2015; UNESCO 2018). This disparity is driven by issues such as a lack of resources and discrimination. Unfortunately, these individuals and their specific needs and experiences are also the most likely to be overlooked within sex education curriculum. Sex educators are beginning to place a stronger emphasis on creating more inclusive programs that not only provide their students with information that is applicable to members of these populations, but that also empower these students and emphasize their right to sexual health.

Increase pleasure. Pleasure is one of the primary reasons individuals engage in sexual activity, but it is largely ignored within school sex education programs (Hirst 2012). Programs that incorporate discussions on pleasure often resonate more with participants and provide them with more skills to navigate conversations about sex and pleasure than programs that do not discuss pleasure (Hirst 2012). For example, worries about pleasure are a commonly reported barrier to using condoms. Programs that address ways to increase pleasure while using an external condom have overwhelmingly demonstrated a greater impact on condom use than programs that focus solely on the health benefits of using a condom (Hirst 2012). Providing students with information and vocabulary surrounding pleasure can help them evaluate what they want, what feels good to them, and how to communicate about that with others.

Content and Characteristics of an Effective Sex Education Program

Content. In 2018, the United Nations Educational, Scientific, and Cultural Organization (UNESCO),

in partnership with other UN organizations and the World Health Organization (WHO), published their international recommendations for sexuality education (2018). The programming they recommend, informed by current research, is comprehensive and should address:

- Relationships
- Values, rights, culture, and sexuality
- Gender
- Violence and staying safe
- Skills for health and well-being
- Human body and development
- Sexuality and sexual behavior
- Sexual and reproductive health

Implementation. For these programs to be as effective as possible, research says they should be delivered by educators who are comfortable talking with students about sexuality and who have adequate training and support from school administrators (Browes 2015; Mkumbo 2012; UNESCO 2018). These classes should be delivered in a mixed-gender group of peers that are of similar age or developmental stage. Facilitation of lessons should be spread out, providing students with sex education each year. The time a school spends on sex education may vary widely, and research indicates that it is important for program planners to address both the quality and quantity that they can deliver to their students. Generally, better impacts correlate with more time spent facilitating, provided that the quality of facilitation is maintained (UNESCO 2018).

The program should also acknowledge the environment in which the curriculum is being delivered. This is particularly important when there are contradictions between what is promoted in a program and what students experience in their daily lives at school, home, and in the community. For example, some students receive information on the harm of sexual harassment or gender violence from school-based programming, while sexual harassment and gender violence continue to thrive as social norms within their school-based peer groups (Browes 2015; Rasmussen et al. 2017). If left unaddressed, contradictions like

this may undermine the program and reduce or even reverse its impact.

Intersectionality. All students are affected by issues like racism, sexism, ableism, heterosexism, and transphobia. This is true even if systemic issues are not readily apparent within a school or in the immediate community surrounding a school. These problems have been shown to directly impact a host of sexual health outcomes, and students should be provided with the tools and information to identify and address them. This information not only helps students face these problems as individuals, but it can also empower them to create more equitable communities.

Information provided in a sex education program should also be actively inclusive of students of different identities and experiences. This can be done by including new information or employing different, culturally appropriate language. For example, to be more inclusive of intersex, transgender, or nonbinary students, educators could replace the phrase “during puberty, girls begin menstruating” with “during puberty, people with ovaries and a uterus usually begin menstruating.” This shift in language is not only more inclusive, but more accurate.

Future Directions

To better achieve the goals of sex education, future programs should continue to improve content and program implementation, connect with other services and organizations, and adopt new and developing technology. Improvements in content and program implementation should continue to focus on providing information on a wide range of topics related to sexuality, empowering students, creating more inclusive content, addressing systemic issues, and supporting individuals delivering the information (Haberland and Rogow 2015; UNESCO 2018). These program goals have primarily been driven by research, which is a crucial tool for improving programs and health outcomes. More research is needed to understand how changes in the above areas may impact students, especially those that are members of more vulnerable populations. More

longitudinal research is specifically needed to understand how these programs may impact students and the communities they live in years and decades after implementation.

Health professionals are increasingly advocating for an integrated system of services to address needs, as programs that are connected with complementary services often see better sexual health outcomes when compared to programs that are not integrated (UNESCO 2018). School-based programs addressing sexual health are no exception. Sex education programs should seek out connections and partnerships with other related services and organizations within a community, such as condom distribution programs, clinics, and LGBTQ+ resource centers. Connected organizations can communicate, ensure they're providing complementary services, and provide more services to a greater number of people.

Sex educators also have the opportunity to integrate new and developing techniques and technology into their classrooms (UNESCO 2018). Technology can improve the reach of formal, trained educators and facilitators through online courses or live streams, providing sex education in a curricular format which students would not otherwise have had access to. This may be especially effective in rural or other areas that are difficult to access.

Conclusion

Sex education is a human right. Sexuality education offered in schools is an increasingly powerful tool that can be used to improve health, reduce inequities, and combat systematic discrimination. The most effective programs deliver accurate, inclusive, positive, and empowering information on a wide range of sexuality topics to students. All adolescents deserve access to sex education programs that educate and support them.

Definition

Sex ratio is the relative number of men to women in a given population

Introduction

The ratio of men to women within a mating population varies significantly across time and culture. Evolutionary psychologists expect, and find, that variations in human sex ratios are predictably associated with differences in human mating strategies, such as changes in sociosexual attitudes, intensity of mate competition (e.g., intrasexual violence), and patterns of courtship and mate choice.

Mating Strategies

Every primate species seems to have a “natural” mating strategy. Some primates are monogamous (e.g., gibbons), some polygynous (e.g., gorillas), and some engage in multimale-multifemale mating as their primary means of reproduction (e.g., chimpanzees; Dixson 1998). The human primate, however, appears to have a diverse and varied menu of reproductive strategies, with different people deploying different strategies as individuals, and within their own lives over time. For instance, although over 80% of foraging cultures have polygynous mating systems (i.e., men may have more than one wife; Marlowe 2003), most men and women within foraging cultures are

officially married to only one other person (Stewart-Williams and Thomas 2013). Moreover, premarital and extramarital sex is common among foraging cultures (Barash and Lipton 2002), as is frequent divorce and re-marriage (functioning as serially monogamous mating systems; Fisher 1998). It appears, humans, unlike most primates, are designed to be flexible and to pursue, across varying times and situations, both long-term and short-term mateships as strategic means of reproduction (Buss and Schmitt 1993; Symons 1979).

The apparent flexibility of humanity's fundamental mating repertoire may stem, in part, from its having a highly *facultative* design. That is, much of our mating psychology may be calibrated to adaptively respond to key developmental, socioecological, and personal contexts (Gangestad et al. 2006). For instance, human mating psychology appears specially designed to shift to a more short-term oriented strategy as in response to stressful attachment experiences during development (Belsky et al. 1991; Ellis et al. 2009) to low levels of pathogens in the local ecology (Schaller and Murray 2008), and, among men, short-term mating is adaptively evoked in response to high levels of personal strength and physical attractiveness (Lukaszewski et al. 2014). In terms of affecting both men's and women's human mating strategies, however, perhaps no contextual factor has turned out to be more influential than the numerical ratio of men and women in the local mating pool (Ember 1974; Guttentag and Secord 1983; Marlowe and Berbesque 2012).

Operational sex ratio (OSR) is defined as the numerical ratio of reproductive-age males to reproductive-age females in a given mating population (Emlen and Oring 1977). In humans, "high" OSRs refer to populations with more reproductive-age men than women, whereas "low" OSRs refer to populations with more reproductive-age women than men (Pedersen 1991). Because OSRs can influence the availability of potential mates, unbalanced OSRs can affect sexual selection pressures by heightening the intensity of intrasexual competition within the sex that is more numerous and heightening the intensity intersexual selection among the rarer

sex (Trivers 1972). Put simply, because there are fewer of the rarer sex to go around within unbalanced OSR populations, the plentiful sex has to compete more intensely to fulfill the stronger desires of the rarer sex (Guttentag and Secord 1983). When there are many more men than women, for example, the plentiful men must intrasexually compete more forcefully against one another to effectively provide the highly selective women with what they desire (Barber 2001a; Stone et al. 2007).

In humans, women generally desire higher levels of commitment before consenting to sex than men do (Simpson and Gangestad 1991). As a result, evolutionary psychologists expect, and have found, that higher OSR contexts (within which women are rarer than men and can command the mating marketplace; Guttentag and Secord 1983) are associated with increases in indexes of long-term mating and "sociosexually restricted" attitudes and behaviors (Pedersen 1991; Schmitt 2005). For instance, historical analyses have found higher marriage rates, lower divorce rates, fewer illegitimate births, fewer teen births, and higher paternal investment when OSRs are higher (Barber 2001a; Guttentag and Secord 1983; Kruger and Schlemmer 2009; Pedersen 1991; Pollet and Nettle 2008). Higher OSRs also are historically associated with men enhancing their appeal to more highly selective women through heightening their masculinity, such as sporting more mustaches and beards (Barber 2001b).

Cross-culturally, higher OSRs are empirically associated with increases in indexes of long-term mating and "sociosexually restricted" attitudes and behaviors in men and women (e.g., lower levels of sociosexuality, Kandrik et al. 2015; Schmitt 2005). Again, this is presumably because when women are rare they are better able to command the mating marketplace and impose their greater interest in high-commitment mating (Pedersen 1991). High OSRs across cultures also are associated with more relaxed long-term mate preferences by men, possibly in order to facilitate the acquisition of the less numerous and highly selective women partners (Stone et al. 2007).

Experimentally, manipulating impressions of OSRs by making men appear more common

than women is associated, as expected, with more long-term mating and restricted levels of sociosexuality (Moss and Maner 2016). Also as expected, when men are rarer than women and men are therefore better able to command the mating marketplace, such low OSRs are historically, cross-culturally, and experimentally associated with the opposite – increases in indexes of short-term mating and more “sociosexually unrestricted” attitudes and behaviors (Baumeister and Vohs 2004; Guttentag and Secord 1983; Pedersen 1991; Schmitt 2005).

Further support for the view that human mating psychology is designed to strategically shift in response to OSR variation comes from studies of intrasexual competitiveness and direct mating effort (Arnocky et al. 2014; cf. Schacht et al. 2014). For instance, higher OSRs are historically and cross-culturally associated with higher levels of men’s intrasexual aggression and violence (Barber 2000, 2003; Hudson and Den Boer 2004). Across 120 cities in the United States, higher OSRs were associated with indexes of men’s impulsiveness, such as owning more credit cards and having a higher amount of debt on the credit cards they do have (Griskevicius et al. 2012). Experimentally, higher OSRs are linked to men focusing on immediate rewards, rather than saving for the future and appear to lead men to spend more money during courtship (e.g., paying more for engagement rings, Griskevicius et al. 2012). Higher OSRs seem to evoke tendencies in men to diversify financial resources less and instead concentrate investment in high-risk/high-return options when making lottery, stock-pool, retirement-account, and research-funding decisions (Ackerman et al. 2016).

There is growing evidence that women also adjust their mating efforts in response to shifts in OSRs (Dillon et al. 2017). For instance, Arnocky et al. (2014) experimentally manipulated perceived OSRs and found women who were exposed to a low OSR mating market with a scarcity of men reported more intrasexual competition, jealousy, and willingness to aggress indirectly against a mate poacher compared to those exposed to an abundance of males. Dillon (2012) found already-mated women exposed to a low

OSR mating market tended to feel more positively toward their current partners, including finding them more attractive than women randomly assigned to high OSR mating markets with a surplus of men. Durante et al. (2012) demonstrated across historical data and experimental manipulations that lower OSRs are associated with women (especially low mate value women) seeking high-paying careers and delaying the start of their families. In contrast, women in higher OSR nations tend to marry early as a reflection of a more restricted sociosexuality (Trent and South 2011).

There is much work to be done in elucidating the precise mechanisms by which OSRs influence human mating psychology. At present, it appears likely that OSRs play key roles in evoking adaptive changes in men’s and women’s sociosexuality, intensity of intrasexual mate competition, and patterns of intersexual mate choice. When OSRs are high, both men’s and women’s sociosexuality is restricted, men engage in more intense intrasexual competition, and women’s intersexual mate choice is more selective. When OSRs are low, sociosexuality and indexes of short-term mating tend to increase as men become the rarer sex and are able to command more value in the mating marketplace, and women engage in greater intrasexual competition to fulfill the desires of the opposite sex.

Conclusion

Given the extant evidence from cross-cultural, historical, and experimental studies, variations in operational sex ratios appear to be associated with changes in human mating behavior, including predictable features of sociosexuality, intrasexual mate competition, and intersexual mate choice.

Ossietzky University of Oldenburg, Oldenburg,
Germany

Synonyms

Adult sex ratio; Committed relationship; Operational sex ratio

Definition

- Sex ratios are defined as the number of men per 100 women (in pre-defined age groups).
- We define long-term mating as a mating strategy in which men are seeking a partner for a long-term relationship.

Introduction

Human mating strategies are not fixed but constitute facultative responses to developmental,

individual- and population-level, social, and ecological circumstances. As a consequence, men's preferences for and likelihood of engagement in long-term mating have been shown to be subject to variation across contexts (Schacht and Kramer 2016; Uggla and Mace 2017) ► “Sex Ratio” by D. Schmitt.

A growing body of literature identifies the sex ratio as such a contextual factor for mating behavior. The sex ratio is commonly defined as the number of men per 100 women, yet operational definitions vary across the literature. Variants include the adult sex ratio (ASR) which is calculated on the basis of age cohorts between puberty and menopause and the operational sex ratio (OSR) which is defined as the ratio of unmarried adult men to unmarried adult women in a population. In monogamous societies, OSR and ASR should be highly correlated. In either case, low sex ratios indicate a relative oversupply of women, whereas high sex ratios indicate a relative oversupply of men.

Mating Behavior and Sex Ratios

Evolutionary and social scientists conceptualize the local number of males and females as a mating market which is driven by supply-and-demand dynamics. Following this conceptualization, an oversupply of one sex on the mating market increases mating opportunities for the other, scarcer sex. A common hypothesis posits that both women and men's likelihood of engaging in a sexual or romantic encounter or relationship increases with the relative number of opposite sex partners. This perspective is often referred to as the “demographic opportunity thesis” (Adkins et al. 2015). A number of scholars argue that an imbalance of mating opportunities further translates into asymmetries in bargaining power on the partner market (Arnocky et al. 2016; Schacht and Kramer 2016; Uggla and Mace 2017). When either sex outnumbers the other, the scarcer sex has a larger pool of potential partners to choose from and thus a higher likelihood to find a partner that best fits his or her own preferences. On the other hand, individuals of the more common sex

face tougher competition to find a partner. In view of such intensified competition on the partner market, an optimal strategy may be to cater to the preferences of scarce partners.

Parental investment (PI) theory predicts that due to women's higher physiological parental investment (gestation and breastfeeding), men and women have evolved different mating psychologies. Although both men and women exhibit short- and long-term mating strategies across life course stages and socio-ecological contexts (David P. Schmitt – ► [Sex Ratio](#)), PI theory suggests that, on average, men exhibit a higher tendency toward short-term and uncommitted mating than women (Robert Trivers: ► [Parental Investment and Sexual Selection](#)). Against this background, sex ratio theory suggests that the ability to realize these sex-specific mating preferences is co-determined by partner availability. When males are in short supply, they are more likely to have their preferences met because women compete for a partner by appealing to male mating preferences. Given the assumed higher average preference for short-term mating in males, this implies that, in a low sex-ratio context, males can behave more promiscuously, offer little parental investment, and still be able to find a partner. However, when women are less plentiful, men will appeal more to female preferences and be more willing to commit to a single partner. In sum, local sex ratios are theorized to shift incentives to pursue different partner market strategies and to display different mating behaviors (Arnocky et al. 2016; Schacht and Kramer 2016; Uggla and Mace 2017).

Empirical Evidence

Empirical evidence only partially supports the prediction that men are less likely to commit themselves to a single relationship when partner markets are favorable, i.e., sex ratios are female-biased. Until recently, the bulk of empirical studies analyzed indicators of female mating behavior to infer on male mating behavior. Specifically, studies analyzed associations of sex ratios with rates and timing of women's marriage or rates of single-mother households and interpreted low rates of marriage or two-parent families as

indicative of low male relationship commitment. However, recent studies undertook steps toward a more direct measurement of male mating behavior. For instance, Schacht and Kramer (2016) analyzed male marriage rates from US census data and found that male abundance correlates with higher shares of men being married. In addition, the authors report that high sex ratios are associated with lower rates of extramarital fertility and female-headed households. Overall, the authors interpret these results as indicative of higher rates of male long-term mating strategies when women are scarce. However, inferences on individual-level correlations from aggregated data bear the risk of ecological fallacies. Testing hypotheses on individual behavior patterns should ideally involve individuals as units of analysis.

Studies in the field increasingly address this concern by analyzing individual-level data but yield contradictory results. One study shows that men in female-biased US census tracts were less likely to cohabit with a romantic partner and had a greater number of dating partners (Warner et al. 2011). Similarly, a relative abundance of women in their community increases the likelihood for Chinese men to engage in premarital intercourse (South and Trent 2010). However, there is also evidence suggesting that ASRs are inversely associated with the male propensity to form a committed relationship. For instance, Eckhard and Stauder (2018) report that education and age-specific sex ratios correlated positively with union formation among men in Germany. Moreover, Uggla and Mace (2017) report that while *female* cohabitation is associated with male-biased sex ratio wards in Northern Ireland, *male* cohabitation did not correlate significantly with ward-level ASRs in Northern Ireland. A study of union formation in Mexico finds neither significant associations between female nor between male union formation and municipality sex ratios (Parrado and Zenteno 2002).

Discussion

One explanation for these contradictory findings could be that union and marital formation are only

weak indicators for long-term mating strategies when social costs and stigma associated with separation are low. Consequently, associations of sex ratios with indicators such as marriage or premarital intercourse might vary across time and space. Also, associations should be sensitive to different operationalizations of similar indicators. For instance, marriage and cohabitation might reflect different levels of commitment across societies.

Another point to be made is that studies of long-term mating strategies should seek to include larger portions of individuals' relationship trajectories beyond just the transition to *first* marriages, cohabitation, or parenthood. Besides these early transitions, for instance, the stability of pair bonds, or the likelihood for infidelity to one's partner, might be relevant correlates of sex ratios as well. Men might at first commit to a partner but only later choose to opt out of the relationship to that partner. This follows from the higher opportunity costs men in a numerically favorable partner market have for staying in a relationship as compared to men in a less favorable partner market. Empirically, Arnocky et al. (2016) could show, for instance, that partnered men exhibited stronger infidelity intentions in an experiment when led to believe that mates are abundant instead of scarce. Similarly, female-biased sex ratios correlated with greater risks of separation for both men and women in an analysis of register data from Northern Ireland (Uggla and Mace 2017).

A further explanation for contradictory findings could be that regional or local sex ratios do not correspond closely with individual experiences of partner availability. Experimentally, participants have been shown to adapt in response to clues of local sex ratios. For instance, men were less favorable to engaging in casual, uncommitted sex when treatments suggested that potential female partners are scarce versus plentiful in an experiment (Arnocky et al. 2016). However, explicitly providing participants with information on local sex ratios in a lab experiment might not have high external validity for how individuals normally perceive partner availability on the partner market. Social everyday interactions in modern societies

are structured into social foci, such as workplaces, schools, colleges, hangouts, or friendship networks. Sex ratios in these local contexts might not necessarily be representative of the local proportion of men and women: even in a high-sex-ratio society, for instance, male and female networks may be highly segmented by sex and gender. Consequently, individuals likely perceive partner pools selectively based on their respective social foci. This is supported by a recent study of nationwide survey data which finds no correlation between a variety of local sex ratio measures and subjective partner availability in Germany (Filser and Preetz 2019). If indeed local sex ratios are only loosely, if at all, correlated with individual perceptions of sex ratios, this may be one explanation for the contradictory results on the purported association between sex ratios and male mating behavior. In general, operationalizing sex ratios more closely based on what individuals actually perceive as their partner market might yield more consistent results when studying social outcomes of sex ratios.

Observational studies of sex ratios in social foci such as campuses seem to be a promising approach to circumvent such problems. For instance, sex ratios of colleges might be a closer approximation of students' peer group sex ratios and therefore capture subjective experiences of partner availability more accurately. Yet, empirical evidence on campus sex ratios remains contradictory as well. For instance, female-biased college campus sex ratios have been reported to correlate with more frequent hookups and a higher number of sexual partners. Moreover, when female students outnumbered men on campus, both men and women were less likely to consider love a necessary prerequisite for sex, an indication for a less restrictive socio-sexual orientation (Adkins et al. 2015). However, this is at odds with a recent study which finds that in high schools in which girls outnumber boys, students report a less sexually permissive normative climate and girls report less casual sex when compared with their counterparts at schools in which boys outnumber girls (Harknett and Cranney 2017). Of course, both studies differ in the age structure of their study

populations. However, the opposite associations suggest that more research on school and campus sex ratios is warranted.

Conclusion

Sex ratios have been theorized to affect men's propensity for long-term versus short-term mating behavior. Specifically, men are predicted to be more committed to a single partner when alternative options are scarce, i.e., sex ratios are male-biased. While there is some experimental and observational evidence to support these predictions, the literature remains contradictory and fragmented across the social and biological sciences.

More research is needed to establish a better understanding of how sex ratios affect mating. Specifically, future research should focus on individual-level data instead of studying population-level indicators to avoid ecological fallacies. Analyses of individual-level data further enable researchers to study potential variation of behavioral responses to imbalanced sex ratios across social status groups or other individual characteristics (Uggla and Mace 2017). In addition, more longitudinal analyses are necessary to substantiate how sex ratios affect mating strategies across the life course. Finally, paying closer attention on how responses to comparable sex ratios vary across cultural contexts seems indispensable. Social norms concerning sexual activities and union formation, particularly social sanctions against pre- or extramarital intercourse, may limit the viability of mating options.

While both theoretical and empirical clues that sex ratios are associated with men's long-term mating exist in the literature, an integrated and empirically well-substantiated model has yet to be established.

Sex Segregation

Janine Bosak and J. Brueckner
Dublin City University, Dublin, Ireland

Synonyms

[Gender segregation](#)

Definition

Unequal distributions, or separation of people according to their biological sex.

Introduction

Sex segregation, or gender segregation, is an enduring phenomenon that is typically defined as an imbalanced distribution of men and women within a given locational dimension such as occupation, professional specialization, industry membership, or education (Charles 2015). While absolute separation between the sexes is much less common in the Western world today than it was in the past, relative sex segregation is still a prevalent phenomenon in the workplace. The present entry focuses on *occupational sex segregation*, which is the separation of men and women into different jobs or different roles within organizations (Harcey and Prokos 2017).

Types of Segregation

There are two fundamental types of sex segregation – *horizontal sex segregation* and *vertical sex segregation*. Horizontal sex segregation refers to men and women's unequal dispersion across different occupations, for example, teachers, doctors, lawyers, cashiers, nurses, and construction workers, or across different occupational specifications, such as pediatric surgeon versus heart surgeon or science teacher versus arts teacher. Horizontal segregation shows at least three distinctive

features, which are (1) the magnitude of gender distributions across disciplines, (2) the crowding of women into a narrower range of professions than men, and (3) the likelihood of men and women sharing an occupation. In contrast, vertical sex segregation refers to men and women's unequal dispersion within an organizational hierarchy such as first-level manager versus executive manager, school teacher versus headmaster, or assistant professor versus full professor (see Charles 2015).

In general, sex segregation has substantially dropped since the early 1970s but reached a relative plateau in the 1990s. Vertical sex segregation is a nearly universal phenomenon that occurs within almost every profession and culture (Gutek 2001). Even today, women's presence within different hierarchical levels in the workplace still takes a pyramid-like shape representing an increasing gender imbalance at higher stages of the career ladder. However, through a variety of governmental, organizational, and societal initiatives focused on improving gender equality in the workplace, vertical segregation has decreased moderately in industrialized countries, and invisible leadership barriers for women (i.e., glass ceiling) have become more permeable (Bosak and Kinahan 2014; Charles 2015). In contrast, horizontal segregation has not changed considerably over the past decades. Instead, occupations continue to be prone to gender labeling or gender typing. More specifically, gender typing implies that roles and responsibilities are assigned based on a traditional division of labor, wherefore men and women occupy positions with traditionally gendered job descriptions (Costen 2012). Thus, certain occupations like truck drivers or construction workers are still categorized as “men jobs,” whereas other professions such as nurses or primary school teachers are perceived to be “women jobs” (see Charles 2015).

Causes and Consequences of Sex Segregation

Research presents several explanations for occupational sex segregation (e.g., Harcey and Prokos 2017), among which the three most common

explanations for occupational sex segregation are (1) evolutionary, (2) economic, and (3) sociological. The *evolutionary perspective* explains sex segregation with innate biological differences between men and women that arose from human evolutionary history (Browne 2006). According to Buss (1995), these biological differences emerged because in human evolution men and women have faced “recurrently different adaptive problems” (p. 19). More specifically, for large parts of human history, men faced the adaptive problem of hunting, whereas women faced adaptive problems of gathering and caring for offspring. The evolutionary perspective thus argues that men and women are fundamentally different and therefore equipped to fit occupations, which are congruent with their biological characteristics.

In contrast, the *economic or human capital view* of sex segregation argues that differences in men and women’s hierarchy and role in an organization are attributable to differences in their human capital, that is, their specific KSAOs (knowledge, skills, abilities, and other characteristics; Costen 2012). Because women are often more invested in domestic work, childcare, and eldercare than men, it is claimed that they develop less human capital. According to the rational choice concept, households are likely to focus on the career development of the party with more human capital as primary breadwinner (Blackburn et al. 2002).

Stemming from sociology and social psychology, *social role theory* emphasizes men and women’s adaptation to a traditional division of labor in which men typically served as the provider and women as the caretaker (Eagly 1997) rather than biological or evolutionary positions. Specifically, social role theory views traditional gender roles as “socially constructed sets of ideas that are firmly grounded in the requirements of a society’s productive activity” (Eagly 1997, p. 1381). As an explanation for occupational sex segregation, social role theory suggests that the traditional distribution into different social roles resulted in the generation of gender stereotypes. For example, women are perceived to be more communal (e.g., caring, helpful), while men are believed to be more agentic (e.g., assertive, dominant); thus, gender

role stereotypes reinforce traditional sex segregation, in which women typically occupy roles that are characterized by nurturing acts, care, and helping, whereas men usually occupy positions that are characterized by assertiveness and dominance (Eagly and Wood 2016).

Other explanations for sex segregation focus on factors pertaining to employer behavior and the broader societal context. For example, the increased availability of part-time work is viewed as facilitating increased segregation, with child-rearing women leaving their occupational path for part-time hours and lower-skilled, feminized work (Blackwell 2001). Other work emphasizes the influence of governmental policies such as maternity leave, anti-discrimination, and protective legislation on occupational segregation (Chang 2004).

While sex segregation always entails an unequal distribution of men and women, it does not automatically imply discrimination (Browne 2016). It is however strongly linked to gender inequality (Hesmondhalgh and Baker 2015), with typical jobs and occupations performed by women rather than men being valued and paid less. For example, research using US census data from 1950 to 2000 found substantial support for the view that increased feminization of occupations diminishes their relative pay, which is indicative of the devaluation of jobs with large shares of females (Levanon et al. 2009). The mere existence of sex segregation and thus people’s observation of women and men in different roles further limit (a) women’s and men’s autonomy and individual choices and (b) collective flourishing. For example, Bosak and Sczesny (2008) found that, despite comparable qualifications and skills, female business students felt less suitable for an entry-level leadership position than their male counterparts because they believed to possess less of the masculine attributes typically ascribed to leaders. These internalized gender beliefs limit women’s choices and career behaviors and contribute to the underrepresentation of women in traditionally male-dominated roles such as leadership. The same applies to men with ambitions to pursue female sex-typed roles albeit the proportion of women wishing to pursue nontraditional occupations is more pronounced than that of men, with

occupational segregation thus disadvantaging women more than men. Sex segregation in the workplace might also constrain organizational performance and collective flourishing. Research has found that a positive association between gender diversity and firm performance is only achieved in the presence of a critical mass of women rather than “token women” on corporate boards (Joecks et al. 2013). Further, Bettio and Verashchagina (2009) state that, at a macroeconomic level, “segregation may be exacerbating skill shortages insofar as it impedes the efficient reallocation of male and female workers and distorts the allocation of future flows of workers” (p. 46). Finally, occupational sex segregation both builds on and, in turn, fosters cultural beliefs about women and men, with these stereotypes shaping gender-differentiated aspirations and choices – reinforcing the prevailing pattern of occupational segregation by sex (Hesmondhalgh and Baker 2015).

Sex Segregation and Social Change

Some scholars adopting functionalist and neo-institutionalist views of gender inequality believe that sex segregation will gradually erode due to economic (e.g., gender inequality is argued to be inefficient and not compatible with liberal capitalism) and cultural (e.g., nation-states show increased commitment to gender equality and non-discrimination) factors (see Charles 2015). Other scholars emphasize the persistence of cultural beliefs or stereotypes about men and women, which justify, rather than undermine, the existing sex segregation in employment and hierarchy in organizations (Bosak and Eagly 2014). According to social role theory, people’s beliefs about women and men follow from their observed role behaviors. The slow but gradual change in women’s social position and roles in society thus might foster a change of gender stereotypes over time. For example, Bosak and Sczesny (2011) found that those participants, who believed that more women would move into leadership roles over time, also expected the perceived incongruity between women and leaders to erode in the future. In general, vertical and horizontal forms of sex

segregation are strengthened by descriptive and prescriptive gender norms about what women and men are like and should be like, which contribute to gender bias and discrimination in the workplace, and men’s and women’s own gender identity, which has implications for their job search behavior and career decisions (Bosak and Eagly 2014; Bosak and Kinahan 2014). Another factor limiting change pertaining to sex segregation is women’s compared to men’s continued greater involvement in domestic work and child-rearing, which – paired with a lack of family-friendly practices in organizations and/or high childcare costs – makes women often leave their careers or perform non-elite, less skilled work (Blackwell 2001).

Interventions directed to reducing sex segregation have therefore focused on educating individuals about stereotypes and biases through diversity training and unconscious bias training with somewhat positive effects. Other interventions aim to change the gender composition of study programs, occupations, and leadership positions through organizational policies, government mandates, and initiatives including affirmative action, gender pay reporting, the introduction of gender quotas, and the formal institution of family-friendly work-life policies (see Eagly and Heilman 2016). While these direct interventions at organizational level can yield positive effects, research (e.g., Heilman and Haynes 2006) has also shown that they can foster (i) resistance in organizations who might seek to opt out of the mandate; (ii) negative reactions among non-beneficiaries who feel unfairly treated, and (iii) stigmatizing effects toward beneficiaries (e.g., the professional success of some women may be unfairly perceived by some to be the result of affirmative action rather than performance). Finally, interventions might also entail increasing women’s human capital via education and training in nontraditional occupations and leadership capital via opportunities to gain leadership experience.

Conclusion

Sex segregation refers to an imbalanced distribution of men and women within a given locational dimension such as occupation, professional

specialization, industry membership, or education. Vertical occupational segregation, i.e., over (under) representation of women and men into elite versus non-elite roles, can be distinguished from horizontal segregation, i.e., over (under) representation of women and men across professions. Both horizontal and vertical sex segregation are strongly associated with gender inequality and contribute to the prevailing gender pay gap through (a) a general devaluation of work that is performed by women and (b) women's higher prevalence in non-elite jobs. The prevailing sex segregation can be explained by evolutionary, economic, and sociological theories. It has implications and potential costs at individual and macroeconomic levels. Many organizations and policymakers, therefore, aim to reduce occupational sex segregation via various, sometimes controversial, interventions.

Definition

Sex switching is the process by which an organism changes sexual characteristics, including gonads and gamete production, from one sex to another.

Introduction

Sex switching occurs when an organism changes from one sex to another. This switch is

accompanied by a shift in gamete production and reproductive strategy corresponding to the new sex. Sex switching often occurs due to environmental pressures that inhibit the reproductive prospects of one sex over another, such as when one sex is overabundant within a group or when mates of the opposite sex are otherwise difficult to find. Although sex switching is relatively common in plants, it is almost exclusively restricted to fish and invertebrates in the animal kingdom. There are three types of sex switching: protandry, protogyny, and bidirectional.

Evolution of Sex Switching

The evolution of sex switching is often understood via sex allocation theory, which predicts the patterns by which organisms in a population are likely to divide sex distribution of progeny (Charnov 1982). According to sex allocation, the abundance of one sex makes the production of the other sex beneficial as the scarcer sex will have a larger pool from which to draw mates. As selection favors one sex over the other with more ample mating opportunities and reproduction, the sex ratio within the population will shift back toward equilibrium. This phenomenon is frequency-dependent natural selection working on the ratio of sexes within a population (Charnov 1982). Protandrous species often display male-biased sex ratio, and protogynous species often display a female-based sex ratio (Allsop and West 2004). Thus, sex switching is favored when it increases the fitness of an organism by altering its sex later in its lifetime or development. Complementary to this theory is the size-advantage model which states that sequential hermaphroditism will be favored where size and sex combine to predict reproductive success (Ghiselin 1969; Warner 1975). Across species that demonstrate sex switching, it is most likely to occur later in development, usually when the individual is around 72% of maximum body weight (Allsop and West 2003).

True sequential hermaphroditism is limited to fish and invertebrates in the animal kingdom (Charnov 1982). It should be noted that sex

switching is differentiated from transgenderism in humans. Sex switching is part of a reproductive strategy in which individuals achieve fecundity as the assumed sex after changing. This is contrasted to transgenderism in humans, which is categorized by dysphoria in an individuals' perceived gender not matching their biological sex. Gender reassignment surgeries do not alter reproductive abilities as these individuals remain only able to produce gametes of their birth sex. Similarly, sequential hermaphroditism must be distinguished from simultaneous hermaphroditism. As the name suggests, simultaneous hermaphroditism consists of concurrent possession of male and female reproductive systems. Both systems may be functional, and simultaneous hermaphrodites may be able to reproduce using male or female gametes. Sometimes, simultaneous hermaphrodites can self-fertilize, a behavior found even in the animal kingdom (Jarne and Auld 2006). This is contrasted to sequential hermaphroditism, which is characterized by a sex switch by the organism whereby it gives up reproductive abilities as one sex to become another.

Protandry

Protandry occurs when an organism begins life as a male, but changes into a female later in life. Often, this sex change is a response to environmental cues in species in which female fecundity increases with age (Warner 1975). Anemonefish of the *Pomacentridae* family, especially the *Amphiprion* subfamily, are among the best studied groups of protandrists (Avisé and Mank 2008). While some protandrous species mate at random (Warner 1975), others live and reproduce according to a predictable hierarchical social structure. In one of the best understood species, *Amphiprion percula*, this structure consists of one dominant breeding male, one breeding female, and several submissive juvenile males. Dominance is determined by size with the dominant female being the largest in the group (Fricke and Fricke 1977). Sex change is triggered by the removal of the dominant female (e.g., by death), after which the breeding male changes into the

breeding female and the dominant juvenile male undergoes a period of rapid development to become the breeding male. Although non-dominant males do not breed, it is theorized that they persist within this mating strategy because of the potential for reproductive benefits from future mobility within the social structure (Buston 2004).

Protogyny

Protogyny occurs when an organism begins life as a female, but changes into a male later in life. Protogyny is much more common than protandry and bidirectional hermaphroditism (Allsop and West 2004). Because the relationship of size and sexual output typically favors large males more than large females, selection pressures in protogynous species are on males (Avisé and Mank 2008). Protogynous species often feature harem social structures in which a dominant male secures reproductive access to a number of females, which constitutes the bulk of reproductive behavior (Black and Grober 2003). In many species, such as the rock wrasse (*Halichoeres semicinctus*; Adreani & Allen 2008) initial phase (i.e., immature, small) males demonstrate differing mating strategies from terminal phase (i.e., mature, large) males, with terminal phase males most often attempting to defend territory in pursuit of pair mating or spawning. Terminal phase males in protogynous species maintain advantageous mating benefits over initial phase males and non-changing females, which favors the inclusion of sex changing in the gene pool (Warner 1975).

Bidirectional

Bidirectional hermaphroditism is the least common form of sex switching in the animal kingdom and is characterized by changing from one sex to another, followed by reverting to the initial phase sex. Bidirectional changes can be either protandrous or protogynous and often occur in response to a change in status within the social hierarchy of a group (e.g., *Lythrypnus dalli*; Rogers et al. 2007). This plasticity of sex is

often manifest by changes in the group, whereby an alteration in the social status of an individual can result in a change in sex. In some species, individuals can change their sex to accord with their social position many times. In these cases, where changes in the social structure are frequent, individuals may retain the gonads of the non-functional sex (e.g., *Trimma okinawae*; Yamaguchi and Iwasa 2017), effectively making them simultaneous hermaphrodites. Despite the potential benefits, retaining the gonads of the non-functional sex is costly and far from ubiquitous among bidirectional hermaphrodites (e.g., *Paragobiodon echinocephalus*; Yamaguchi and Iwasa 2017).

Conclusion

Sex switching, or sequential hermaphroditism, is used as part of the mating strategy of some organisms, but is limited to some fish and invertebrates in the animal kingdom. Species may be born male and switch to female (protandry), female and switch to male (protogyny), or more rarely both (bidirectional). Typically, sex changing occurs later in an organism's development and is a result of environmental cues. Population sex ratios are usually biased toward the initial phase sex in sex-switching species. The ability to change sex increases the fitness of an organism by increasing reproductive opportunities that might otherwise be limited by remaining its birth sex, thus increasing the likelihood of sex switching being included in subsequent generations.

Introduction

Our knowledge of the world comes from the history of mankind. Through the ages, civilizations have risen and fallen, and cities have developed and vanquished; the earliest accounts of mankind tell tales of conflicts and conquests. When we look back into history we see a reflection of the lives of people. One distinct pattern is visible: an evolutionary desire to leave one's genes in the population and secure one's lineage, to create a stable environment for offspring to live their lives in the attained glory of their ancestors, and to establish an identity by conquest. In short, this shows us that sex, power and conflict have been present in society throughout our evolution. Over the millennia, the argument about differences in sex has evolved significantly. Challenges to the patriarchy are being observed and people are breaking down stereotypes, challenging their own potential and diluting gender roles from one side to the other side of the continuum. Yet, there is increasing gender-directed violence, intolerance and hate (Buss and Malamuth 1996). The great epics such as *Mahabharata*, *Ramayana*, *The Iliad* and *The Odyssey* all contain central themes of sex, power and conflict. Moving forward from classical to modern literature, sex, power and conflict have been central themes of stories and poetry. The recent worldwide megahit fantasy epic *The Song of Ice and Fire* (written by George R. R. Martin)

and its television adaptation, *Game of Thrones*, also majorly revolve around this topic. From classical to contemporary times, sex, power and conflict have surrounded the world in various versions with and without alterations and remain captivating topics for academicians, writers and the general public. This article briefly discusses the concepts of sex, power and conflict.

Definitions

Sex: According to the *Merriam Webster English Dictionary*, sex can be defined as “the sum of the structural, functional, and sometimes behavioural characteristics of organisms that distinguish males and females” (Merriam Webster 1996). Alternatively, it can be defined as an act of intercourse between two or more people; its synonyms include coitus, intercourse, fornication, congress, copulation, and mating.

Power: This means an ability to act or produce an effect; to give impetus to; to be able to utilize strength. Power is synonymous with authority, clout, command, grip, dominion and mastery (Merriam Webster 1996).

Conflict: This can be defined as a fight, battle or war; a difference, opposition, contradiction or failure to be in agreement or accord; or a struggle as a result of incompatibility between one's needs, drives, desires, or external or internal demands (Merriam Webster 1996).

Sex, power and conflict in the great epics: The story of *Ramayana*, when we look at it, revolves around the main themes of sex, power and conflict. Rama was the son of Dasharatha, the king of Ayodhya. Dasharatha had three wives and four children. The son of the first queen, Kaushalya, was Rama; the son of the second queen, Kaikei, was Bharat; and the third queen, Sumitra, had two sons: Laxman and Shatrughna. During the illness of King Dasharatha, Kaikei cared for him and he bestowed three promises upon her. Kaikei requested him to fulfil these promises when the time came. When the children grew up and it was time for the coronation of Prince Rama, Kaikei asked Dasharatha to fulfil his promises to her, and she, with the guidance of her maid Manthara, asked

him to send Prince Rama into exile for 14 years so that her son would become the king (Pattanaik 2013). This led to the death of King Dasharatha, but, to honour his father's promise, Rama, with his wife and brother Laxman, left and went into exile. A bias towards Queen Kaikei from her husband led to a shift in power in the family and created an internal conflict within the royal family of Ayodhya. Thereafter, we observe the main theme of *Ramayana*: the abduction of Sita by Ravana, which resulted from the proposal of marriage by Surpanakha (Ravana's sister) to Laxman. The story after that revolves around the power and conflict of Ravana, who was an immensely great and powerful king, and Prince Rama in exile. The final result of the destruction of Swarana Lanka (Golden Lanka, currently known as Sri Lanka) and the death of Ravana marks the victory of good over evil. This theme is still related to sex, power and conflict at a basic level. Even at the end of *Ramayana* we see the plight of Queen Sita as she is forced to undergo the Agni Pariksha (a trial by fire) for being in Ravana's place for so long to prove her dedication to her husband. She is driven out of the kingdom in a pregnant state and later gives birth to twins, Luv and Kush, who stop the Ashwamedha Yagya horse to finally reunite with their father. However, when Queen Sita is forced to go through another Agni Pariksha to prove her dedication to her husband, in her plight, she goes into the earth, never to return. All of this is done to please the people of the kingdom. We find that sex, power and conflict are central themes of this story, and we observe that they have led to devastation, loss of life and other calamities happening to the protagonists (Buck and Triest 2000). The same themes can be observed in the great epics of *The Iliad*, *The Odyssey* and *The Epic of Gilgamesh*; there we can observe that the lust of Prince Paris led to the war between Greece and Troy. Even the gods were involved in showcasing their power; they created various situations and interfered in human feelings, and the ultimate result led to the devastation of Troy (Kullmann 1985). Carefully observed, this shows how men can be manipulated by lust, sex and greed; how glory can be a goal of one's life; and how conflict can bring about devastation and turn cities into dust.

Evolution Relating Sex, Power and Conflict

Before the theory of evolution was published by Charles Darwin, there was a hypothesis that humans were created by a being of superior intellect and power (creationist theory), although this had no substantial evidence. Darwin's theory stated that there were spontaneous variations in reproduction, leading to diversification, and that individuals with favourable mutations would survive, while those with unfavourable ones would perish. This gave an opportunity to explain a lot of the current scenarios and development of various taxa in the animal kingdom (Dawkins 1986).

The Biological Battle of the Sexes

Human beings are considered to be special animals, as we are users and makers of tools and use vocal and pictorial signs to communicate universally, including use of grammar and other advancements. Recent discoveries have changed the perception of humans as being so unique, as we now understand more secrets of the behaviour of other animals. Unlike many organisms, humans reproduce sexually, which leads to adaptation to the environment and variation of traits in the gene pool. Changes in genetic material mean that a mother may be adapted to her surroundings but her offspring may not have the capacity to adapt. This can be explained by the example that if men who are physically powerful kill other men who are not as powerful, the average life expectancy of men will come down and more aggressive traits will be present in the next few generations, but as less strong people live longer, their traits will persist for a longer time in the generations to come (Buss and Malamuth 1996). The scientific literature describes human beings as "dioecious," meaning that they come in two varieties – male and female – primarily, and in terms of reproduction, their combined genetic material can only give rise to another human being. To maintain traceable and desirable genetics, humans have developed the concept of marriage; although the offspring have their own unique genetics, their history can usually be traced back through their morphologies. If we look into the investment

made by women biologically, their eggs are bigger than the male's sperm and, because of the mammalian form of reproduction and lactation, mothers invest a lot of time and energy in their offspring. Observing the dioecious nature of humans, there is an innate battle of the sexes. This is also a reason why humans focus on parental investment. The differences in the roles of both sexes vary biologically, and nature gives both perspectives, with agonistic as well as antagonistic factors between both sexes (Buss and Malamuth 1996).

Marriage and humans: Marriage is a phenomenon observed in all human societies. It legitimizes the relationship in an economic manner as well as a reproductive manner, it gives the couple socially accepted access to sexual reproduction, and it also keeps society intact by providing legitimacy for the rearing of children. Marital obligation goes far beyond just conception: it also gives rise to a lot of expectations of a varied nature; moreover, marriage is a process of cross-generational relay of heritable material. Although marriage is a method of producing and rearing children, marriages are often observed to fail with or without attainment of the reproductive goal. There are similar such unions in the animal kingdom, but the investment of both parties is seldom so apparent, thus making marriage a uniquely human phenomenon (Buss and Malamuth 1996).

Marital Conflict

The union of marriage has been thought to be both economic and reproductive in nature, but the companionship designed through marriage often does not work out. The reasons can be arbitrarily divided into three categories: when the female invests in relationships other than the marriage, when the male invests more in out-of-marriage relationships, and power clashes between the partners. Female partners may not be satisfied with the investments that their partner makes in the relationship; they may be attracted to more comforting partners, and this may give rise to conflict with the current marital partner. Here, the male often resorts to physical strength to gain control and power over the female. In the

other case, it has been observed that when the male wishes to resort to sexual relationships outside the marriage and starts investing more in another relationship, with or without the desire to mate and procreate, the female feels the dearth of emotional investment, which leads to dissatisfaction between them. The third reason is often related not to sexual or mating desires but to social power-related struggles; this kind of conflict often occurs because of excessive intervention on the part of in-laws from either side, and this probably relates to most of the married couples in the world. There can be issues of conflict between the partners regarding children; it has often been observed that a mother wants her partner to invest more in her biological children that he is willing to give, leading to conflict and violence against children and women alike. This leads to a conflict of rearing in which males who do not father the children are not interested in investing their resources in the children of that mother, leading to marital conflict and suffering of the offspring (Buss and Malamuth 1996).

Violence against women: Recent worldwide statistics have shown that one in three women experiences violence in their lifetime and 30% of women are victimised by their intimate partners. Globally, 38% of murders of women are committed by their male intimate partners (WHO 2017). This shows us the grave nature of the conflict that occurs, and fatal outcomes affect not only the women but also their children and the whole family. Violence against women is also caused by the struggles of sex, power and conflict. Patriarchal societies often give rise to a feeling of dominance among men, with women being considered property; thus, to maintain the stance of power to discipline them, men often resort to use of power and coercion. When this is met with resistance, they resort to conflict and inflict injury and pain on their victims (women).

Sexual Harassment

Sexual harassment has been one of the most talked-about topics in recent times. Most workplaces have developed policies regarding sexual harassment as a policy protocol (Government of India 2015), and regulatory acts have been

introduced to prohibit and prevent sexual harassment in the workplace. Sexual harassment has been a phenomenon causing women to abstain from public life and has created fear among women since ancient times. The Renaissance brought about a change in the conditions and the behaviour of women. Then came the Industrial Revolution, and the West transformed completely after that. As the number of women increased in the workplace, workplace exploitation started for them as well. The patriarchal societies of the world have discriminated against women in terms of their working hours, equality of pay and benefits. These trends are also seen today. Many women desperate to climb the ladder of success submit to harassment for an increase in salary or because of pressure to avoid losing their job (Government of India 2015). This phenomenon is worldwide in nature. It is representative of the biological feud between men and women. Although women have increased their socio-economic status, they are still dominated by the males of the world, who do not want to share their power with females, thus creating the essence of conflict. People in the workplace are often in an advantageous situation and exploit their superiority and power to obtain sexual advantages, to breach the morals of female employees or to maintain their level of power, creating a situation of hostility in the workplace and making it difficult for women to work.

Offenders and Victims of Sexual Coercion

Sexual coercion means forcing someone to commit a sexual act with the perpetrator. This in itself brings out a very violent nature or force applied to sexual activities for the victims. Often it has been observed that the victims are well known or stalked by the perpetrator with a intention to violate their self-esteem and to hurt, exploit or kill them; just as a measure to control their behaviour so that the victim loses their social status or brings shame upon their kin and other members of their social group; or to express their power over the victim. Most of the time, the perpetrators are actually successful in achieving their intentions: the victims suffer injuries, broken or shattered self-esteem, and loss of social status and

desirability as mates for others, which has a huge impact on the victims' lives. Often it has been observed that they suffer from anxiety disorders and post-traumatic stress disorder (Thornhill 1996). Commonly, females are the victims of sexual coercion, leading to a disturbed state of mind and a broken spirit. This can be evolutionarily observed in other mammals; for example, when the alpha male of a pride of lions is defeated in a fight, the winning lion automatically gains access to copulate with the females of the pride. Similar behaviours have also been observed in humans and other animals. We can observe that sexual coercion has been used by humans to create an exhibition of power over those who are defeated.

The Feminist Perspective

A discussion about the feminist perspective cannot take place without an elaboration of feminism. Feminism essentially is a collective, social, political and technological ideology to establish equality for both sexes. Feminism deals not with the phenomenon of the things that currently exist but with the phenomenon of what should be. The feministic ideology fights fiercely with the concept of the superiority of one sex to another; it advocates for equality for both sexes and supports all efforts to achieve this in all aspects: social, political, legal, educational, work and benefits. It aims to show the unseen and neglected part of society, which needs attention to bring about stability in the world.

Is Rape About Sex or Violence?

There has been a long-standing and ongoing discussion about rape. The word "rape" is something we understand as a man using force to commit copulation with a female. A 1993 description by Campbell states that rape is actually a calculated act of violence, which is mainly committed in cold blood not to let off steam or to express anger but as an act in which the aggressor actually feels no anger towards the victim (Greathouse et al. 2015). This discussion has fuelled a discussion about the goal of rape. The majority of theorists

have said that the goal is to have sex, but feminist theories suggest that it is more of a method of aggression used by males to achieve the goal of dominance and exert the power of control over their female counterparts (Buss and Malamuth 1996). Examples of marital rape show that many times, males have sex with their wives whenever and wherever they wish in order to exert complete control over their lives and to showcase their dominance of the females. Thus, rape is a violent act with the aim of destroying the integrity of the victim, and nothing less.

Substance Use and Its Impact on Perception and Behaviour

The discussion on substance use is a very important one. Psychoactive substances have been known to man from time immemorial. People use them for recreation and many other purposes. Substances such as alcohol were considered in ancient Greece to be aphrodisiac (Kullmann 1985). Since then, humans have experimented with them. Biomedically, alcohol is known to cause lack of inhibition and distort the judgement of people consuming it; initially, this has an effect on the sexual desire of people. When we observe the patterns of sexual violence, the characteristics commonly observed are that both men and women usually drink in heavy amounts, there is a history of sexual abuse in childhood, and most men who rape have a notion that women who drink are easily available targets for sexual exploitation. Both men and women party a lot and go to bars. Men use alcohol as an excuse for inappropriate behaviour. Alcohol can lead to cognitive and motor disturbances, misleading both men and women to perceive that they are being led on (Abbey et al. 2001). Thus, alcohol and other substances can be a reason for an increase in the incidence of violence directed towards women.

Sexual Politics

Politics is the science of governance; we can observe the play of sex, power and conflict in a very integrated manner. The evolutionary sciences tell us that aggressive and dominant traits are observed among the males of many hominids. There is a strong chance that such men father more

children; thus, the dominating trait is more commonly observed among men around the world, giving rise to a patriarchal system in society. Polygamous societies tell us tales of men having many wives. There are societies where women have accepted the dominance of men and it is observed that less coercion is needed from the men to achieve the goals of sex, dominance and labour (Thornhill 1996). The oppressive nature of the men has led them to acquire land and fight among themselves to acquire more women and children who will help them in providing for the males of the house. When we look at classical texts and poetry, we observe this pattern of acquiring new lands among the leading societies. Acquiring more women has also become a status symbol among men to showcase their power. This has led to the politicising of sexual preference, making males the source of the strength of the family and thus bringing in a linear hierarchy of sons and making women merely a source to get more power. When we look into politics, we observe that certain monarchs marry the daughters of other monarchs to establish political gain for both houses, thus making women a commodity to be traded for power or acquired to showcase power (Buss and Malamuth 1996). This has been a trend to establish and forge political ties. There are also accounts that after a king or ruler was defeated, his wives were taken away by the aggressors and raped; here, sex was made a weapon to punish the losers and harm their integrity.

Conclusion

There are three gates to the self-destructive hell:
lust, anger and greed. – Lord Shree Krishna

The words of Lord Krishna in *Mahabharata* resonate with this topic immensely (Roy 2010). The words are *lust*, which leads to *sex*, and this can be attributed to suppression of the other sex (suppression of the female by the male) to achieve reproductive or other goals. This leads to a feeling of superiority and a sense of strength (*power*), which leads to a feeling of *anger*. Anger can be triggered by a threat from the other sex or from the

same sex, in order to acquire something that is a desire or a possession. This leads to a feeling of *greed*, which can manipulate a man to attack or create a situation of *conflict*. Conflicts occur between and within nations or states, between people and within the individual. They can lead to a self-destructive hell. We may argue that sex, power and conflict have been present in human society throughout our evolution, but the ultimate effect of these phenomena cannot shape the future of mankind for the better. When people are not given equal opportunities and greed dominates power, then only conflict and destruction can occur. Unless mankind is able to control our innate animalistic desires, sex, power and conflict will remain. To become the superior human that is desired can be achieved only with *equality of both sexes*. *Power struggles* should not be the main issue; rather, *peaceful coexistence* should be. Ultimately, *conflict* should be of the intellect and spirit for growth; conflict among people has brought only destruction and devastation to the world. Since the start of the twentieth century, humans bore the brunt of World Wars I and II, which affected the whole world and led it to the verge of destruction by nuclear weapons. It is to be hoed that understanding of this topic will help people understand themselves and choose a path of self-betterment.

Sex-Differences in Disease Avoidance

Diana Fleischman

University of Portsmouth, Portsmouth, UK

Synonyms

[Gender differences in disgust](#)

Definition

The degree to which men and women avoid cues that indicate contagious illness or that elicit the emotion of disgust.

Introduction

Pathogens, the organisms and viruses that cause disease, are a central adaptive problem for almost all organisms. Pathogens, like bacteria, helminths (worms), viruses, and protozoa, take nutrients from their hosts, the larger multicellular organism. They also shelter in their host and often use the host's own cellular processes to make copies of themselves. While there are many bacteria, microorganisms, and even viruses that do not cause harm to their hosts, pathogens are defined as agents that cause disease and by definition undermine the normal functioning of the host organism.

Because of the constant threat of pathogens, immune systems have evolved in many organisms. Humans and other mammals are equipped to fend off pathogens with a variety of different cellular functions from creating molecules that coat the pathogens (antibodies) to having specialized cells that absorb the pathogens (e.g., macrophages). However, launching immune attacks is energetically costly. Thus, it is in the organism's best interests to avoid being exploited by these organisms in the first place. The way that organisms prevent pathogens from triggering these other physiological defense mechanisms is called disease avoidance.

Disease Avoidance

Disease avoidance is widespread. Even organisms as simple as worms can avoid toxins in their environment. Rodents avoid diseased conspecifics and even rats who are known to eat a wide variety of foods display a “cannibalism taboo,” avoiding eating other rats for the purposes of disease avoidance (Hart 1990). Humans also engage in various disease avoidance strategies common in other species; however, humans are the only species who demonstrate disgust.

Disgust

The central adaptive function of disgust is thought to be to reduce the risk of infection by motivating distance from cues of pathogens. While so-called pathogen or disease avoidance disgust is likely central to its function, disgust also deters mating with humans who do not show signs of good genetic endowment (Tybur et al. 2013). Disgust is measured in humans in a variety of different ways, through word-based questionnaires, through image-based ratings, through measuring disgust facial expressions, and through behavioral tests (for a review see Fleischman 2014).

Differences in Disgust and Disease Avoidance

Decades of research have shown that there are robust sex differences in disgust sensitivity, defined here as the tendency to experience disgust. Women have been shown to be more disgust sensitive than men using verbal measures and across all domains (Fleischman 2014). Specifically in the pathogen domain, women are more disgust sensitive when rating disgusting images (Curtis et al. 2004) and when engaging in disgusting tasks (e.g., eating a piece of feces-shaped fudge) (Rozin et al. 1999). As adults, women are more likely to develop obsessive-compulsive disorder, more likely to present with cleaning compulsions and contamination obsessions (Altemus et al. 2014). In nonclinical samples, women score

higher than men on measures of OCD-related contamination fear (Mancini et al. 2001).

Sexual disgust has been shown to be very different between men and women. In studies using the established three domains of disgust scale, the largest sex difference is in the sexual domain $d(475) = 1.44$ as compared to the pathogen domain $d(475) = 0.32$ (Tybur et al. 2011). Women are less inclined toward casual sex and more disgusted by pornography than men (Koukounas and McCabe 1997). Finally, while sexually aroused men have been shown to have reduced disgust sensitivity, sexually aroused women do not always show this effect and may even show increased pathogen disgust sensitivity (for a review, see Fleischman 2014).

Functional Reasons for Sex Differences in Disgust Sensitivity

Compared to men, women have faced unique circumstances over evolutionary history that may have led to heightened pathogen disgust sensitivity. Women show changes in immunity across the menstrual cycle and as a function of pregnancy that make them vulnerable to disease. Women also must protect children and infants who are vulnerable from disease, perhaps making pathogen disgust sensitivity more important (Curtis et al. 2004). Finally, women are uniquely able to pass on sexually transmitted and other infections to their offspring during pregnancy, birth, and lactation (Fleischman 2014; Madkan et al. 2006). Men's greater propensity for risk taking more generally might also be contributing factor to their relatively lower disgust sensitivity.

There are several adaptive reasons why women might have heightened sexual disgust. Women can have fewer offspring than men and have a greater burden of parental investment. Thus, they have less to gain from engaging in promiscuous sex. If sexual disgust serves to prevent one from engaging in sexual activity with someone who is not genetically fit, men have less to lose and thus lower disgust sensitivity in this domain. Anatomical differences between men and women lead to large differences in rate of infection and disease

burden for sexually transmitted disease. Women have a greater area of mucous membranes and experience more damage during intercourse. In women, the fallopian tubes open into a central pelvic cavity making them much more likely to get systemic infection from bacteria that are sexually transmitted. Women with a sexually transmitted infection are much more likely to die or become sterile (Madkan et al. 2006).

Conclusion

Selection pressure has acted differently on men and women with regard to disease avoidance. Disgust, the uniquely human emotion thought to have evolved specifically for disease avoidance, tends to be greater in women than in men. In particular, sexual disgust sensitivity is greater in women. This is likely due to disease risk and burden from sexually transmitted infection as well as greater obligate parental investment.

Sexism

Sylis Claire Alexandra Nicolas
Oakland University, Rochester, MI, USA

Synonyms

Gender inequality; Patriarchy; Sexual control; Sexual discrimination

Definition

Sexism is discrimination or prejudice directed toward an individual based on his or her gender or sex.

Introduction

Women and girls tend to be recognized as the primary victims of sexism across cultures. For example, worldwide, women earn less, have less representation in politics, lower participation in the labor force, and receive less education than their male counterparts (United Nations Development Programme 2015). However, men and boys are also affected by sexism. For instance, men are more likely to be the victims of corporal punishment, capital punishment, aggression, violence, have higher mortality rates, and are less likely to gain child custody (see Benatar 2012).

Contemporary social movements such as *feminism* seek to eliminate inequality between the sexes in employment, education, politics, social roles, and reduce the occurrence of sexual coercion and violence that disproportionately affects women. Evolutionary accounts of patriarchy, or widespread male domination, have been offered by some theorists (e.g., Buss and Malamuth 1996; Smuts 1995) in an effort to better explain the suppression of women's autonomy by males and identify the contexts in which it is most likely to occur. Evolutionary biologists and psychologists propose that patriarchy can be contextualized as arising from the interaction between evolved psychological mechanisms and social/cultural contexts. Two foundational components that evolutionary theorists have argued underlie patriarchal practices include: the control of women and girls' sexuality and the coevolution of men's intrasexual competition and women's partner preferences. These features of patriarchy are discussed below, in regards to lower resource control (e.g., economic resources, property) and higher rates of sexual victimization experienced by women (Clinton Foundation 2015), respectively.

Control of Female Sexuality

An evolutionary perspective predicts that human males will monitor and attempt to control the sexual behavior of females in effort to assure their paternity, as observed in other pair-bonded, sexually reproducing species (Trivers 1972). Over

human history, men have faced the adaptive problem of determining whether their children are indeed their own genetic offspring, or the offspring of another man that resulted from an infidelity committed by their female partner. Thus, it is hypothesized that attempts to control female sexual behavior represent strategies by men to ensure their paternal certainty, and these behaviors evolved because they contributed to men's reproductive success (i.e., men who were better able to avoid being cuckolded were more likely to pass on their genes).

Evidential support for this theory comes from observable patterns in physical and sexual violence perpetrated against women and girls. For example, millions of women and girls are subjected to severe genital mutilation procedures that are psychologically and physically harmful to ensure their chastity (World Health Organization 2016). These procedures are frequently practiced because they are believed to guarantee a woman's virginity and reduce her libido, thereby ensuring that she will remain faithful to her husband (World Health Organization 2016). Often, in cultures practicing female genital mutilation women who do not undergo these surgeries face social rejection and are no longer considered viable for marriage.

An evolutionary perspective also predicts that increasing the likelihood of paternity certainty underlies violence, sexual coercion, and rape directed at women. Research stemming from evolutionary theory suggests that men's fear of cuckoldry is strongly related to these violent acts. Specifically, both physical and sexual violence (i.e., rape) directed at men's intimate partners are predicted by accusations or suspicions of their partners' infidelity (reviewed in Kaighobadi et al. 2009). It is hypothesized that physical aggression towards men's romantic partners may function as a threat against or punishment for committing infidelity. Additionally, partner rape could be an unconscious attempt to minimize the chance of insemination by another male by means of displacing rival sperm (see ► [“Sperm Competition,”](#) this volume). In fact, rape is frequently perpetrated by intimate partners and husbands (see Clinton Foundation 2015; Kaighobadi

et al. 2009). Importantly, these findings do not justify men's aggressive acts towards their partners whatsoever; instead, evolutionary theorists seek to better understand the motivations behind such violent behaviors in order to more effectively predict and prevent them.

Coevolution of Men's Intrasexual Competition and Women's Partner Preferences

Another key component of patriarchy hypothesized to contribute to the control of human females is the coevolution of intrasexual competition by men (i.e., competition between men for access to mates), and women's mate preferences for partners with resources. Buss and Malamuth (1996) suggested that men's greater access to and control of resources is attributable to the discrepancy in selection pressures on men and women to acquire them. Specifically, because women more than men prefer romantic partners who have access to economic resources such as income, men have evolved to compete for access to resources as a means of attracting female mates, whereas comparatively, women have not (see Buss and Malamuth 1996). Consequently, the inequality between men and women with respect to control over economic resources, manifesting in a higher worldwide poverty rate and unequal participation and compensation in the workforce (United Nations Development Programme 2015), is a likely by-product of this sex difference. To counteract this inequality, Smuts (1995) recommends establishing institutional policies (e.g., laws) to guarantee women's access to resources, such as property, in societies where economic disparity between the sexes is more pronounced.

Conclusion

Evolutionary theorists have proposed evolved functions of behaviors underlying the most pervasive manifestations of sexism, including the unequal distribution of economic resources and sexual victimization experienced by women and

girls across cultures. With its unique insights into human psychology and behavior, an evolutionary framework can be used to gain a more thorough understanding of sexism and reduce sexist attitudes and practices (e.g., Smuts 1995). Although historically there has been less attention given to sexism perpetuated against boys and men (see Benatar 2012), an evolutionary perspective may shed light on some of the specific disadvantages they face. For example, Archer (2009) hypothesizes that intrasexual competition may account for why they are disproportionately the victims of violence.

It is critical to note that addressing sex-based inequality will be most effectively accomplished by studying the interaction between the biological and environmental contexts (e.g., personality traits, situational factors). Moreover, an evolutionary perspective does not discount the importance of human learning and social change in rectifying these injustices. There is evidence to suggest that sociopolitical movements can be effective. For example, feminist movements are associated with declines in the rates of crime and rape since the 1990s (Pinker 2011). Indeed, Smuts (1995) asserts that instituting policies that offer women legal protection against sexual violence/coercion and against men's control over their economic assets will likely facilitate gender equality. Accordingly, cultural and social revolutions, including those focusing on women's interests, have been responsible for a worldwide decline in violence in the past 10,000 years. This indicates that men also stand to gain from more equitable sociopolitical circumstances. Nevertheless, Benatar (2012) believes it is unlikely that sexism will be completely eradicated when one sex no longer dominates the other and suggests that legal protections also be made in favor of men and boys where they are specifically disadvantaged.

Sexism Against Male

- [Second Sexism](#)

Sex-Role Inventory, The

M. Pilar Matud
Universidad de La Laguna, La Laguna, Spain

Synonyms

[Gender role inventory](#)

Definition

Sex role (or gender role) refers to the characteristics, expectations, and values associated with being male or female in a particular culture. Sex-role inventories have been designed to assess people's endorsement of masculine and feminine characteristics.

Introduction

The first self-report to measure masculinity-femininity (M-F) was published in 1936 by Terman and Miles. It was tacitly assumed that masculinity was normal and natural in males, yet not in the case of females, and the parallel was held true for femininity (Ashmore 1990). This construct became popular and widespread in the field of psychology, and M-F scales were included in new omnibus personality inventories published in the following three decades. So far, a variety of instruments to evaluate sex roles and other gender-related constructs have been published in different countries across the world. This entry focuses on the one of the pioneering and most extensively used ones ever since its publication in 1974: the Bem Sex-Role Inventory, developed by Sandra L. Bem.

The Bem Sex-Role Inventory (BSRI)

The BSRI (Bem 1974) is a paper-and-pencil self-report instrument that asks a person to indicate, by using a 7-point scale, how well each of 60 different attributes describes him or her. The masculinity scale is made up of 20 of those characteristics, namely, "acts as leader," "aggressive," "ambitious," "analytical," "assertive," "athletic," "competitive," "defends own beliefs," "dominant," "forceful," "has leadership abilities," "independent," "individualistic," "makes decision easily," "masculine," "self-reliant," "self-sufficient," "strong personality," "willing to take a stand," and "willing to take risks." The femininity scale consists of 20 characteristics ("affectionate," "cheerful," "childlike," "compassionate," "does

not use harsh language," "eager to soothe hurt feelings," "feminine," "flatterable," "gentle," "gullible," "loves children," "loyal," "sensitive to need of others," "shy," "soft spoken," "sympathetic," "tender," "understanding," "warm," "yielding"). The remaining 20 items are fillers (e.g., "adaptable," "conventional," "jealous," "sincere," "solemn," "inefficient"). The respondent is unaware of these categories and response scale ranges from 1, for "never or almost never true," to 7 being "always or almost always true."

On the basis of his or her responses, each person receives three major scores: a femininity score, equal to the total number of femininity scale points; a masculinity score, equal to the total number of masculinity scale points; and an androgyny score. Subjects whose score is significantly higher on the masculinity scale than on the femininity scale are labeled masculine; those who score high on the femininity but not on the masculinity scale are labeled feminine; those who score high on both the masculinity and the femininity scales are identified as androgynous; and those who score low on both scales are labeled as undifferentiated. Masculinity and femininity scores are independent to one another and "indicate the extent to which a person endorses masculine and feminine characteristics as self-descriptive" (Bem 1974, p. 158).

The BSRI contains a number of features that make it stand out from other scales so far used to evaluate M-F (Bem 1974). (1) It includes both a masculinity scale and a femininity scale, each one containing 20 attributes. Positing that, either from a psychological or a social perspective, masculinity and femininity act against consideration as bipolar ends of a single dimension (whereby a person is necessarily to be either masculine or feminine, yet not both as sexes stand in an oppositional relation), the BSRI represented a new type of sex-role inventory where masculinity and femininity could be evaluated independently. (2) These characteristics were selected as feminine or masculine on the basis of what was culturally defined as gender appropriate in the United States at that time. The BSRI was based on the conception of a conventionally gendered, sex-typed individual "as someone whose self-

definition and behavior are thoroughly intertwined with the stereotyped definition of gender appropriateness in his or her culture” (Bem 1993, p. 119). Judges rated a list of approximately 200 personality characteristics in terms of how desirable they were considered to be for either a man or a woman in American society. (3) It allows the characterization of a person as masculine, feminine, or androgynous. A person is sex typed as either masculine or feminine, whereas the androgynous person was one who displayed both masculine and feminine traits. Psychological androgyny implies the possibility for an individual to be both compassionate and assertive, expressive and instrumental, and feminine and masculine, according to the situational appropriateness of the behaviors; and the individual may even blend these complementary modalities in a single act (Bem 1977). Androgynous people were supposed to have the greatest behavioral flexibility and the best psychological adjustment.

In 1981 Bem developed a short 30-item version of the BSRI that observes a strong correlation with the original BSRI. The short form rules out some items such as “feminine,” “masculine,” “athletic,” “gullible,” or “childlike.” Both the masculinity and the femininity scales consist of ten items, whereas the rest are filler items. Original and shorter versions of the BSRI have been used and validated in various countries and continue to be used, which has proved its usability and value as it allows to claim the relevance of the self-attribution of the stereotypically male and female personality characteristics in different areas, such as the personal well-being, distress, stress and coping, marital satisfaction, leadership, or violence, among others.

Debate Over Bem’s Sex-Role Inventory

The BSRI has triggered discussion of the matter to the point of being criticized on theoretical and methodological grounds. Some controversies have revolved around Bem’s conceptualization of psychological androgyny, which was seen as a form of flexibility that promoted better psychological adjustment. But evidence linking

androgyny and adjustment was mixed (Whitley 1983), although some interest in the topic has continued to be (Martin et al. 2017).

Some authors consider that the BSRI measure of femininity and masculinity is partial as it only assesses the socially desirable gender-related personality traits. They have argued that the femininity scale reflects an expressive or communal orientation, whereas the masculinity scale reflects an instrumental or agentic orientation (Helgeson 2015). Researchers have acknowledged that masculinity and femininity are broad constructs that consist not only of the personality traits but also of behaviors, interests, physical appearance, and occupational preference. But, although BSRI findings cannot be generalized to sex-role behaviors in general, research suggests that instrumentality and expressiveness per se entail important implications. Differences in instrumentality and expressiveness are considered to be core distinctions between women and men, an idea that has been used to account for traditional sex-role ideology (Spence and Helmreich 1980).

The factor structure of the BSRI also was subject to criticism. Findings from factor analysis studies have raised concerns for the replicability of a two-factor structure as it has been found that the masculine construct tends to be more complex in its structure than the feminine (Choi and Fuqua 2003). It has also pointed out that the BSRI may not be suitable for all cultures and time periods, since stereotypes and gender roles vary between cultures and change over time, so it is possible that the BSRI scale items do not match modern gender stereotypes (Donnelly and Twenge 2017).

However, despite men and women roles have changed in recent decades in most societies, these changes highlighting the increased participation of women in the workforce, there is still no evidence of gender equality. Thus, gender division of labor persists, women are underrepresented in top leadership roles in corporations and government, and they still perform most of the domestic work. Moreover, the media continue to depict women and men in very traditional roles, while society keeps making evident the endurance of traditional role expectations and dichotomized gender stereotypes informing the traits, role behaviors,

occupations, and physical characteristics attributed to women and men (Haines et al. 2016).

Conclusion

The Bem's Sex-Role Inventory is a self-report instrument that assesses people's endorsement of socially desirable personality traits that are stereotypically associated with women and men. The femininity scale reflects an expressive or communal orientation, whereas the masculinity scale presents an instrumental or agentic orientation. The original 60-item and shorter versions of the BSRI are still widely used in several countries as a measure of gender-linked expressive and instrumental personality attributes, so the BSRI has proved to be useful so as to claim the importance of the self-attribution of the stereotypically male and female personality characteristics in different areas, such as personal well-being, distress, stress and coping, marital satisfaction, leadership, or violence, among others.

Sex-Specific Link Between Self-Esteem and Mate Value

Christopher Bale

[Romantic desirability](#); [Self-worth](#)

Definition

Self-esteem is an individual's overall evaluation of their worth. It includes both attitudinal and affective components.

Mate value refers to the desirability of an individual as a long- or short-term sexual partner, relative to intrasexual competitors.

Introduction

In their extension of sociometer theory, Kirkpatrick and Ellis (2004) posit the existence of a specific system, the mating sociometer, which functions to monitor and regulate short- and long-term sexual relationships. They suggest that relational status, experiences of romantic acceptance or rejection, and self-evaluations of mate value and its components all influence self-esteem, which then motivates adaptive behavioral responses. There are well-established differences in the determinants of mate value between sexes (Buss 1989), and thus the mating sociometer perspective would predict that there should be sex differences in relationships between specific self-evaluations in domains which contribute to mate value and self-esteem.

Physical Attractiveness and Self-Esteem

One well-established sex difference in the determinants of mate value is the finding that across a variety of cultures, physical attractiveness contributes more to mate value in women than in men (Buss 1989). Consequently, a mating sociometer perspective would predict that physical attractiveness should more strongly predict self-esteem in women than in men. There is a wealth of empirical evidence to support this, and in his comprehensive meta-analysis of the literature, Feingold (1992) found a significantly stronger average correlation between self-perceived physical attractiveness in women than in men.

Moreover, there is evidence from studies of contingencies of self-worth that individuals are consciously aware of this sex difference in the importance of physical attractiveness. Contingencies of self-worth reflect the specific traits which individuals consider most important in determining their self-esteem. Crocker et al. (2003) found that women placed a greater emphasis on physical attractiveness as a determinant of their self-esteem than did men, supporting the prediction that the sociometer system is differentially sensitive to the relative importance of determinants of mate value in each sex.

Social Status and Self-Esteem

While female mate value has been shown to be especially dependent on physical attractiveness, in a number of cultures it has been shown that male mate value is more strongly related to traits which relate to parental investment, such as social status and access to resources (Buss 1989). Thus, a mating sociometer perspective would predict that self-esteem in men should be more strongly related to their wealth and social status than is the case in women. Accordingly, in a meta-analysis of the relationship between self-esteem and socioeconomic status, Twenge and Campbell (2002) found that this relationship was strongest in middle-aged men.

Brase and Guy (2004) also inferred sex-specific links between socioeconomic status, physical attractiveness, and self-esteem in their analysis of demographic differences in relationships between mate value and self-esteem. They found that while both self-perceived mate value and self-esteem increased with age in men (at least until middle age), the opposite pattern was true for women. They suggested that this may reflect the fact that while socioeconomic status tends to increase with age, physical attractiveness decreases, and so these findings would support the existence of a mating sociometer which is attuned to sex differences in the traits most relevant to mate value.

Experimental Research

In addition to the correlational evidence reviewed above, experimental research has demonstrated sex differences in how self-esteem in males and females responds to manipulations of self-perceptions of specific components of mate value.

Pass et al. (2010) took photographs and physical measurements of participants and asked them to complete fake personality assessments. They then provided participants in manipulation conditions with false feedback that they were likely to be repeatedly rejected by potential romantic partners. Half of these participants were informed that this was due to their physical attractiveness

(attractiveness manipulation condition) while the remainder were told that it was a result of their lack of competence and status (status manipulation condition). Female participants in the attractiveness manipulation condition subsequently reported lower levels of self-esteem than women in both the status manipulation and control (no feedback) conditions. Conversely, male participants in the status manipulation condition reported lower levels of self-esteem than men in both the attractiveness manipulation and control conditions. These results support a mating sociometer perspective that self-esteem responds to individuals' perceptions of their mate value and further demonstrate sex-specific links between different components of mate value and self-esteem in men and women.

Conclusion

Correlational and experimental studies support the mating sociometer perspective by demonstrating sex differences in the determinants of self-esteem, which mirror sex differences in the importance of different components of mate value. In particular, as this perspective would predict, self-esteem in women is more sensitive to physical attractiveness, while men's self-esteem is more strongly related to their wealth and social status.

However, at present, there is little research examining how these effects interact with other variables relevant to mating relationships. For example, traits differ in their importance to mate value when considered in the context of short-versus long-term relationships, with physical attractiveness generally being emphasized in short-term relationships (e.g., Regan et al. 2000). There are also sex differences in preferences for short- versus long-term mating, with men showing a relative greater preference for short-term pairings (Schmitt et al. 2001). Accordingly, Penke and Dennisen (2009) demonstrated interactions between measures of men's short- versus long-term mating orientation and their mate value, in predicting their self-esteem. Future studies could profitably further explore similar interactive effects between mate value, mating contexts, and

self-esteem to further investigate the complexities of the mating sociometer.

Definition

The sending of self-made sexually explicit text message, photographs, or videos through electronic media.

Introduction

Scholars have defined sexting in a variety of ways, from broad definitions that include the sending of all types of self-made sexually explicit media (Barrense-Dias et al. 2017) to more specific definitions that are limited to sending photos and videos of particular body parts. Studies also differ in the timeframe; respondents were asked to recall (e.g., 6 months vs. a year), and whether the studies were conducted among adolescents or adults. This discrepancy in methodology has resulted in muddling the accuracy of research findings (Barrense-Dias et al. 2017). For example, the prevalence of sexting defined as the sending of both sexually explicit text messages and photographs has ranged from about 1% to 30% for adolescents and as high as 57% for young adults (Klettke et al. (2014).

While sexting can take place through all types of electronic media, qualitative research finds that it most often occurs through smartphone applications, such as standard texting, Snapchat, or WhatsApp, as some people might feel that it increases their feeling of privacy and security (Van Ouytsel et al. 2017). Although sexting was originally treated by the literature as a deviant behavior, it is now increasingly viewed as a

normative part of sexual communication and expression (Barrense-Dias et al. 2017; Kosenko et al. 2017; Temple 2015).

Motives

For adolescents, sexting can be part of their sexual development and romantic relationship experimentation. Furthermore, it might provide some adolescents with an alternative means to experiment with and to develop their sexual identity (Van Ouytsel et al. 2017). For both adolescents and adults, sexting mainly takes place within the context of establishing a romantic relationship or within an already established romantic relationship, as a sign of love, in order to flirt, or as a gift or surprise to the romantic partner (Barrense-Dias et al. 2017; Englander 2015; Van Ouytsel et al. 2017). Outside of a relationship context, sexting has also been found to occur as a joke, a dare, or as a bonding ritual between friends (Lippman and Campbell 2014; Van Ouytsel et al. 2017). Because of the more distant and asynchronic nature of digital communication, it might make some users more comfortable to express their emotions and sexual desires through digital sexually explicit messages, as opposed to in-person contact (Van Ouytsel et al. 2017). Research has also found that sexting among adolescents could function as a first step towards sexual activity, as it has been found to precede and co-occur with offline forms of sexual contact (Kosenko et al. 2017; Temple and Choi 2014). Longitudinal research has shown that sexting is significantly more likely to precede offline sexual activity, but not sexual risk behavior, among adolescents. Some adolescents could use sexting to indicate their willingness to engage in offline sexual behavior or they could use it to indicate their readiness to take the relationship further (Temple and Choi 2014). Among adults, sexting has also been found as way to engage in sexual hook-ups (Dir et al. 2013).

Risks Associated with Sexting

In some cases, sexting can occur under pressure. Coerced sexting appears to occur most frequently

among (young) women, who report that they felt pressured to engage in sexting by peers, friend groups, or romantic partners (Barrense-Dias et al. 2017; Drouin et al. 2015; Lippman and Campbell 2014; Walrave et al. 2015). A study by Englander (2015) found that 70% of undergraduate college students had experienced a form of pressured or coerced sexting in the 4 years prior to the survey. This study also revealed interesting gender differences with respect to coerced sexting. Males were significantly more likely to report that they never experienced a form of pressure, whereas female students were more likely to report that they always or sometimes felt pressured when engaging in sexting (Englander 2015). Next to forms of explicit pressure and coercion, women are sometimes confronted with more implicit forms of pressure, with men insisting and repeatedly asking them to engage in sexting, making women feel obligated to engage in sexting, or arguing that they have to engage in sexting to prove their love (Drouin et al. 2015; Van Ouytsel et al. 2017).

Next to the potential for sexting messages to occur under pressure, the behavior has gained research attention related to potential reputational risks of engaging in this behavior. Leaked sexting messages could lead to reputational damage for the person who created them (Lippman and Campbell 2014; Van Ouytsel et al. 2017). Qualitative studies identified three major ways in which sexting images could be abused (Van Ouytsel et al. 2017). First, sexting images could be distributed out of revenge, after a romantic break-up. Second, victims could be blackmailed in exchange for additional sexting pictures or offline sexual acts. A third way in which sexting content could be distributed is when boys show the content in order to boast about getting these types of messages. Especially among males, sexting has been found to enhance their social status within the peer group, while a leaked sexting message could harm a girl's reputation (Van Ouytsel et al. 2017).

Conclusion

Sexting takes place through digital media in general and mobile applications in particular. While

sexting may be a normative behavior and can be used to express romantic interest and sexual intimacy, it can also be problematic when it occurs under pressure or when the sexting content is abused by others. Early scholarly research treated the act of merely sending sexting messages as a deviant act, but it is now mostly understood within the need for sexual expression and sexual development from both adolescents and adults alike.

Childhood sexual abuse; Childhood sexual victimization; Sexual trauma

Definition

Sexual abuse (SA) is defined by the involvement of a child in sexual activity the child cannot fully comprehend, for which the child is unable to give informed consent or is not developmentally prepared, or that violates the laws or social taboos of society. Sexual aggression endured in adulthood is termed sexual assault. Perpetrators of SA may be an adult or another child who by age or developmental stage is in a relationship of

responsibility, trust, or power with the child. SA also includes the inducement or coercion of a child to engage in sexual activity or the sexual exploitation of a child (WHO 1999). In the USA, statutory rape laws assert that sexual activities with a minor under the age of consent (varies from 16 to 18) are illegal and therefore considered SA.

Introduction

Research and clinical work indicate that exposure to SA can result in a wide variety of immediate and long-lasting outcomes which can impair an individual's development. This entry summarizes the prevalence of SA, intraindividual and interindividual effects of SA, and the social contexts impacting effects of SA (see Fig. 1).

Prevalence

SA is an international epidemiology with average estimates of 18–20% in women and 8% in men (Barth et al. 2013). Yet, rates vary according to definitional issues the criteria used to define sexual abuse. For example, self-defined SA (i.e., subjective identification as victims) yield lower rates of SA by a ratio of at least 1:2 as compared to rates obtained using an objective definition (i.e., based on legal definition, Vaillancourt-Morel et al. 2016). Based on SA divulged to the US Child Protective Services (2016), about 63,000 children were victims of SA yearly. Yet, this incidence number reflects the tip of the iceberg as only 30% of cases of SA are reported to authorities. Different barriers may refrain disclosure including intraindividual (e.g., internalized blame), interindividual (e.g., dysfunctional family, lack social networks), and social (e.g., stigma) barriers (Collin-Vézina et al. 2015).

In the majority of cases, SA victims knew their perpetrators; 25–35% are abused by family members (including 8–20% by a parental figure), 31–60% by other known abusers, and 5–15% by strangers. The majority of SA is perpetrated by men, and SA often happens in toxic

Sexual Abuse,**Fig. 1** Three levels of repercussion

environments. Indeed, victims of SA are, on average, victims of five other forms of child maltreatment such as violence or neglect. The occurrence of multiple types of child maltreatment is associated with more severe and complex repercussions.

Intraindividual Effects

Psychological Distress: Adapting to Trauma

Victims of SA tend to report dissociation and psychological distress are about three times more likely to experience a major depressive episode and are four times more likely to experience *post-traumatic stress disorder (PTSD)* as adults than nonvictims (Dugal et al. 2016). PTSD includes four cluster of symptoms: re-experiencing (i.e., intrusive re-experiences of the SA, flashbacks or nightmares), avoidance (behavioral, cognitive, or emotional responses to avoid trauma-related distress), negative alterations in cognition and mood (e.g., inability to remember the SA, distorted

cognitions, feelings of estrangement from others), and hyperarousal (i.e., hyperactivation of the sympathetic nervous system with insomnia, irritability, hypervigilance, and a heightened startle response). Psychological distress related to SA may be persistent and cause significant impairment in social, occupational, or other important areas of functioning. Yet, those psychological responses are thought to be, not mere dysfunctional symptoms, but intrinsic mechanisms that serve important functions, such as the avoidance of suffering and the processing of SA-related thought/memories through repetitive activations, until the trauma loses its distress producing characteristics and is processed.

Neurobiological Effects: The Impact of Stress

Neurobiological models suggest that chronic stress caused by traumatic experiences such as SA affects the secretion of cortisol through the hyperactivation of the hypothalamic-pituitary-adrenal axis, which hinders the maturation and

organization of neurons during brain development (see Lupien et al. 2009). Traumas experienced in childhood are associated with hypotrophy (loss of cells) of the hippocampus, which can affect the mnemonic structures. Traumas experienced during adolescence are associated with hypotrophy of the frontal cortex, involved in higher cognitive functions such as reasoning. In addition, hypertrophy (enlargement) of the amygdala is observed in survivors. These three structures play an important role in stress sensitivity and emotional regulation. Through these neurobiological modifications, SA can lead to *stress hypersensitivity*. Therefore, new stimuli (e.g., events) may directly activate the amygdala, leading to impulsive emotional responses (e.g., fight, flight or freeze) without evaluation by the more rational brain structures (e.g., hippocampus, frontal lobe). While those responses (e.g., hypersensitivity) can be adaptive at the time of the SA by promoting survival, they become dysfunctional in the long term. In addition, trauma-related information (e.g., intense fear) tends to become deeply etched into the brain, which in turn promotes the development of PTSD symptoms such as flashbacks. Whenever the individual is confronted with events that activate memories of the SA (e.g., intimate relationships), hyperconsolidated mnemonic residues are brought back to consciousness altering the optimal functioning of the survivors and making them re-experiment the trauma or leading to impaired functioning.

Identity Impairment and Emotion Regulation

SA trauma can impact the survivor's sense of self or identity, including a loss of life goals, confusion about who one "really" is or a view of self as weak and incompetent. Childhood trauma such as SA also tend to inhibit self-awareness, since awareness in this context leads to greater contact with painful trauma-related internal states, and hypervigilance or externally focused attention, associated with survival in dangerous environments leads to sustained absence of internally directed attention. As such, SA survivors may suffer from a relative inability to access a stable sense of identity from which to interact with the external world and experience chronic feelings

of emptiness. These deficits may lead to a generalized lack of knowledge about internal states, insecure and unstable models of self, and poor self-other boundaries. In turn, reduced self-awareness may lead to difficulties in emotion regulation and reduced insight into the effects of SA. This general tendency toward lessened internal awareness and heightened external attention has been referred to as *impaired self-reference* or *other-directness* and is linked to a tendency to rely on others for information about self, including one's worth and entitlements.

Cognitive Disturbances

SA often leads to the development of dysfunctional self-schemas, which are characterized by confusion, shame, deep mistrust, aggressiveness. Besides impacts on internal models of self, survivors often develop cognitive distortions such as guilt or shame and may blame themselves for having somehow provoked or deserved their victimization in attempts to understand why the abuse happened. Such conclusions may lead to self-blame, perceptions of self as bad or unworthy, and distorted views of the perpetrator as benign or blameless, which feeds into the dysfunctional self-schemas and further reinforces them. This cycle often leads to low self-esteem, feelings of helplessness, or hopelessness, as survivors develop and strengthen trauma-based perceptions of themselves and others.

Interindividual Effects

Social and Relational Difficulties

The peculiarity of SA lies in its relational context, and difficulties in social and relational functioning are common ranging from social isolation, trust issues, and detachment from others, to highly anxious attachment, concerns over burdening others, sensitivity to signs of abandonment or betrayal, interpersonal conflicts, and arguments. SA is particularly associated with issues in forming and maintaining intimate connections in adult life, including long-term, stable, sexual-romantic relationships. Indeed, adult SA survivors tend to have difficulties forming close

relationships, have poorer dyadic adjustments, and experience more severe partner violence (Dugal et al. 2016; Godbout et al. 2017). This may occur for several reasons. Survivors who develop posttraumatic numbing may have difficulty experiencing positive attachment affects, leading to decreased experiences of love in interpersonal relationships. In some cases, survivors of SA in their family may not have had the opportunity to develop the relational skills they need to establish and maintain satisfactory intimate relationships. Commitment and intimacy may increase feelings of vulnerability and trigger unresolved issues, emotions, and cognitions associated with SA. Additionally, SA can induce fears of intimacy or vulnerability that, along with a coexisting hunger for connectedness, may lead to ambivalent, chaotic, or short-lived relationships.

Attachment and Negative Relational Schemas

SA, especially if committed by a parental figure or in the absence of support, tends to impact the attachment systems, resulting in chronic, negative expectations and perceptions of the self and others (negative relational schemas), leading to safety, trust, esteem, intimacy, and control issues. SA may also lead to a perception of one-self as unlovable, stigmatized, different, or contaminated, and a view of others as unavailable, untrustworthy, or unavailable in time of needs. These negative models of self and others, thought to reflect the effects of insecure attachment, often persist onto the long-term, producing lasting relational problems.

Revictimization

SA increases the vulnerability to experience further victimization, such as greater risk of psychological, physical, and sexual dating violence and partner violence (Hébert et al. 2017). This could be explained through the *traumagenic dynamics model* (Finkelhor and Browne 1985), where the inappropriate and traumatic development of sexuality and interpersonal relationships accompanied by a sense of shame related to SA make survivors more anxious about their sexuality and lower their self-esteem as valuable intimate partners deserving respect. This could increase their

vulnerability through expectation or tolerance of further violence in relationships or lack of ability to identify potentially dangerous situations, thus increasing their risk of revictimization. Feelings of learned helplessness could also play a part in revictimization. Indeed, survivors may believe they will always be victimized, not feel capable of escaping violent relationship, show inhibited self-protection behaviors when they face situations at risk of victimization. Similarly, the lack of emotional regulation abilities, lack of contact with inner world, and high hypervigilance associated with SA make victims less inclined to detect threats, end a violent relationship, and discriminate between false alarms and real danger, exposing them to greater risks of revictimization.

Sexuality

Sexual impacts of SA fall into two main trajectories: sexual avoidance and sexual compulsion. Sexual avoidance is characterized by sexual aversion and negative sexual attitudes and tends to lead to a wide range of sexual dysfunctions, such as orgasmic disorders. Inversely, sexual compulsion is characterized by an excessive preoccupation with sex, and a conception of sex as necessary to obtain affection. Compulsion tends to lead to sexual relations at an early age, a high number of sexual partners, risky sexual behaviors, and extra-marital relationships.

Social Context: How Culture and Society Shape SA and Its Effects

Social contexts also shape the understanding and repercussions of SA. For example, negative stigmas associated to being a victim of SA are partly promoted by what is known as *rape culture*, defined as a cultural setting in which rape is pervasive and normalized due to societal attitudes about gender and sexuality. Rape culture leads to behaviors such as victim blaming, where victims of sexual crimes are perceived as responsible for their victimization (e.g., by the way a woman dresses). Inefficient judicial responses also impact the perception of survivors that their society is failing in providing a safe and fair environment.

The taboo on sexuality may prevent survivors from disclosing and processing the sexual crime they endured. Well-tailored services available to SA survivors may make a crucial difference in their recovery, while a lack of services may maintain or worsen SA-related negative outcomes. Finally, trauma-informed practices and approaches have determinant effects for survivors. Trauma-informed approaches, grounded in the recognition of the widespread impacts of SA and potential paths for recovery, as well as the signs and symptoms of trauma in survivors, can provide appropriate, *non-retraumatizing*, responses based on scientific knowledge of SA through their policies, procedures, and practices.

Conclusion

SA is not only highly prevalent but also related to a host of durable negative repercussions which often feed into each other, creating a complex negative and dynamic web. Protective intra- and interpersonal factors (e.g., emotion regulation skills, relational support and care), and positive trauma-informed social contexts may however buffer the effects of SA and foster recovery in survivors. Furthermore, these factors may contribute to reducing revictimization and break the cycle of violence in our societies.

Mating prospects of gang members; Sexual motivations of gang members

Definition

A key motivation for men who join gangs is the prospect of increased mating opportunities; men who are members of gangs experience greater mating success, particularly gang leaders.

Introduction

As the lower-investing sex, men are capable of having many more offspring over the course of their lifetime than are women. Indeed, access to mating opportunities is a key limiting factor in men's reproductive fitness. As a result, men are willing to engage in intrasexual competition, sometimes extremely risky and violent competition, in order to increase their mating prospects. One such means of fostering access to women is joining a gang. Qualitative data suggests that this is a key motivation for men who join gangs (Wong 1982), and survey data shows that gang members, especially their leaders, do indeed experience greater mating success than non-gang members (Palmer and Tilley 1995). A more detailed evolutionary account of this phenomenon is described below.

Parental Investment and Sexual Selection

Men and women display clear evidence of distinct reproductive strategies, owing to differences in

their obligatory parental investment (Trivers 1972). Given their relatively small investment, men's reproductive fitness can be maximized by increasing their number of sexual partners. However, women have a large obligatory investment in offspring that places greater constraints on their reproductive capacity. Thus, men's ability to maximize their reproductive fitness is dependent on their sexual access to females. This engenders a high degree of intrasexual competition among men in order to gain access to women, with women expressing greater interest in long-term mates, and a high degree of discretion in selecting short-term mates.

Men may increase their appeal to women by increasing their status, prestige, and reputation. Women may be attracted to men with high status, as it indicates their ability to acquire resources that can be used to help provision shared offspring. High status may also indicate the ability to protect a woman and her offspring from predators and conspecific threats, particularly in uncertain and harsh environments (Snyder et al. 2011). Thus, even if it entails great risk, men may be predisposed to engage in behaviors that have the potential to increase their status. This provides an explanation for the tendency for men to seemingly *over-react* to challenges to their status; a violent response serves to protect their reputation (Daly and Wilson 1988).

Gang Membership and Sexual Access

Membership in gangs may serve a similar function to that of the male coalitions of humans' hunter-gatherer ancestors. Members of gangs and coalitions are often connected by kinship; they work together to protect a territory and defend their group's resources. Moreover, they may engage in offensive aggressive behavior against other groups to increase their access to resources. The tendency for gangs to be very violent and to engage in illegal activity is likely a result of the low socioeconomic status of the members and the lack of opportunities to ascend a status hierarchy using legal means. Thus, for men with few other opportunities, gang membership

may provide a means to acquire status and increase mating access.

Qualitative reports from gang members suggest that at least some of their motivation for joining gangs is the prospect of increasing one's sexual access to women (Padilla 1992). Indeed, the men who join gangs are typically between the ages of 14 and 24, when sexual drives and mating goals loom largest (Palmer and Tilley 1995). Increased sexual access to women may be used as an explicit recruitment tool by existing gangs or may be readily observed by outsiders in the community (Palmer and Tilley 1995). Sexual access may result from the increased prestige and access to resources afforded to gang members and recognized as desirable by women outside of the gang. Additionally, qualitative reports from gang members discuss having ready sexual access to female gang members (Covey et al. 1992), though female gang members are relatively rare compared to that of men.

The expectations of increased sexual access are borne out by data examining reports of gang members as compared to non-gang members (Palmer and Tilley 1995). Individuals reported on the numbers of sexual partners in the last 30 days for a study originally conducted to examine an outbreak of STDs in Colorado. On average, members of gangs reported a significantly greater number of sex partners during this time period than did non-gang members. However, this effect was driven in large part by the number of partners of the highest status members of the gang. Indeed, two gang leaders reported 10–11 sex partners in the past 30 days, a number that exceeds the number of sexual partners for most men over the course of a year.

High status within a gang may be afforded to those men willing to act in the most risky and violent means (Campbell 1993), behavior that is then rewarded by a greater number of sexual partners (Buss 2011; Palmer and Tilley 1995). These findings are reflective of a broader pattern in which high-status males are viewed as more attractive by females. For example, females find men displaying greater dominance and social presence as more attractive (Gangestad et al. 2004). A similar pattern is observed among

younger males, in which bullies that demean and hurt weaker individuals are often the recipients of greater resources (Buss 2011) and mating opportunities (Connolly et al. 2000; Volk et al. 2015).

Conclusion

The theories of parental investment and sexual selection suggest that the mating strategies of males and females differ due to men's lower parental investment which necessitates increased access to mating opportunities as an avenue to maximize their reproductive success. Therefore, men, more than women, will engage in intrasexual competition to improve their likelihood of obtaining mating opportunities. With female preferences for males of high status and access to resources, males may participate in risky behaviors such as gang involvement to compete for mates when other opportunities are limited. Research on gangs indicates male gang members have increased sexual access to women, particularly among higher-ranking leaders. Thus, men participate in dangerous activities that improve their status and, therefore, their mating prospects.

Definition

Sexual interaction with a person considered a friend, but not a romantic partner.

Introduction

Sexual access can come from a variety of sources as sexual interaction can involve short-term (i.e.,

no desire for an ongoing relationship) or long-term mating (i.e., sex representative of closeness and loving) goals or all points in between (Buss 1995). Although they can range from strangers to spouses, sexual partners are typically known and liked others (Perlman and Sprecher 2012). As a consequence, cross-sex friends (CSFs) seem like a natural choice to fulfill this role (among heterosexuals at least). Friends typically know each other well, have developed a close relationship, and, put simply, like one another. Friendships are characterized by warmth, closeness, and intimacy (both psychological and communicative). If friends are intimate communicatively (e.g., self-disclosing personal information on a variety of topics), then it would seem that sexual interaction should follow.

The reality of how platonic and sexual interaction mix is considerably more complicated than our simplistic view would suggest. In particular, the interplay of sexual access and friendship has changed dramatically over the past half century. The traditional view, dominant in the mid- to late-twentieth century, drew a strict boundary between friendship and sexual engagement. The dominant narrative suggested that crossing that boundary was, effectively, asking for trouble. In fact, sexual interaction was typically described as being inconsistent with the very notion of friendship. In the past few decades, that stigma has eroded (or at the very least, shifted). Friends are engaging in sexual interaction in a variety of contexts and under multiple labels. As a consequence, the primary goal of this entry is to review contrasting literatures from the past 50 years as it relates to sexual interaction between friends.

Twentieth-Century Views on Sexual Access and Friendship

For much of the twentieth century, dominant social narratives depicted sex as almost exclusively linked to love and romantic relationships. The dominant script on college campuses throughout 1950s and early 1960s was “abstinence” as sex was considered inappropriate outside of marriage (Reiss 1967), particularly for women. Traditional views of sex created a double standard where women were

(and still are) encouraged not to be too sexually active, as it may lead to negative labels of promiscuity, ultimately hindering their chances of securing a long-term mate (Bogle 2008). Given the sexual revolution of the late 1960s and beyond, the dominant sexual norm on college campuses shifted such that sexual interaction was considered appropriate in both marriage and intimate premarital relationships (i.e., representing a relational orientation; Sprecher 1989). Although a recreational orientation (i.e., sex outside a close intimate romantic relationship) also became more popular during these years, it was derailed somewhat by the AIDS crisis of the 1980s such that it remained less prominent than the relational orientation (Sprecher 1989).

Social norms in the mid-to-late twentieth century suggested, “love and sex are fused together in the ideology of romance” (Werking 1997, p. 29). For both men and women, marriage was the desired relational goal and represented the standard against which all other relationship forms were compared. As relationships developed (from dating to courtship to engagement or cohabitation), partners’ behavior more closely approximated that which occurs in marriage. For example, the sexual script suggested that development of psychological and communicative intimacy between partners would match sexual intimacy. In short, as partners’ relationship became closer (i.e., more closely resembled marriage), the intimacy of their sexual interaction would increase to match (Bailey 1989; Werking 1997).

Given the link between relational development and sexual intimacy, partners’ sexual interaction was thought to generate several important relational changes. For example, sex involved passion, attraction, and consummation such that it represents and motivates a joining of selves (both physically and psychologically). Thus, sexual interaction erodes, and eventually eliminates, boundaries between partners. Moreover, as romantic and sexual relationships become more intimate, partners become progressively more interdependent, relying increasingly upon each other for sexual and personal interactions. Thus, sex in romantic relationships can create feelings of possessiveness and jealousy toward others considered potential romantic threats.

For much of the twentieth century, the egalitarian and open bonds that characterize friendships were considered different (even antithetical) to those that join romantic partners. For example, friendships are relationships among equals, whereas romantic relationships were seen as reflecting society’s patriarchal bias (reflected, e.g., in the sexual double standard). What is more, friendships were generally considered “attraction of the spirit” (Werking 1997, p. 30). Finally, friendship is not typically considered exclusive, as participants are free to form outside friendships, romantic relationships, and work relationships.

Sexual interaction between friends was considered problematic at best (and abhorrent at worst) because it complicated their open bonds. Sexual interaction was thought to create changes that were diametrically opposed to the very nature of friendship. Sex effectively obliterates boundaries between partners and creates a desire for union and merging that generate possessiveness and jealousy. Friendships, on the other hand, are built upon a respect for partners’ separateness and an ability of either friend to engage in other relationships.

Although sex in friendships was seen in very negative terms, some positives were thought to come from this sexual attraction. In fact, physical and sexual attractions are both relatively common motivations for forming CSFs. For instance, participants found romantic attention from a friend to be validating of their attractiveness and added a certain “zing” to the relationship (Werking 1997). Sexual interaction, however, was considered best left implicit. Indeed relatively few friends explicitly discussed the issues related to attraction, sexual desire, or the state of their relationship (Baxter and Wilmot 1985). Although there are positive aspects to (implicit) physical and sexual attraction in CSF, actually acting upon those feelings was strongly and consistently frowned upon.

For the better part of the twentieth century, scholars assumed that sexual interaction between friends was both rare and taboo. At the turn of the millennium, however, several studies challenged that claim. For example, reports indicated that a fairly large proportion of college students (e.g., between 49% and 62%) have engaged in sexual

behavior with an otherwise platonic friend (Afifi and Faulkner 2000; Reeder 2000). Afifi and Faulkner (2000) probed this percentage of college students and uncovered that over half of them engaged in sexual activity with their friend more than once. Moreover, these authors found that nearly 60% of CSFs who engaged in sexual experimentation eventually transitioned into a romantic relationship. Attraction in CSFs comes in many different forms, such as romantic, objective sexual (attractive in general, but not to me), subjective sexual (attractive to me), and platonic (Reeder 2000). This is important because, as noted in the same study, subjective attraction in friendships leads to quicker relational deterioration of friendship.

Perhaps because of the perils that CSFs encounter in the face of sexual attraction (Bailey 1989), the recent flurry of scholarship indicates that removing love and romantic overtones from sexual interactions creates a new way of *doing* CSFs. The emergence of *hookup culture* (Bogle 2008) and *friends-with-benefits relationships* (e.g., Mongeau et al. 2013) allows friendships to exist on a fluid spectrum, rather than being categorized as sexual or nonsexual. Thus we now turn to the literature that accounts for the twenty-first-century perspective on sex within friendships.

Modern Views on Sexual Access and Friendship

In the past two decades, scholarship suggests that (even though dating, courtship, and marriage still occur) multiple forms of nonexclusive, but sexual, relationships are becoming increasingly normative (Afifi and Faulkner 2000; Bogle 2008; Mongeau et al. 2013). Indeed, whereas it was once common to wait between 9 and 22 weeks to engage in a first act of sexual intercourse (Perlman and Sprecher 2012), couples (including CSFs) are now having sex with minimal (or perhaps no) prior interaction (Bogle 2008). The prevalence of sex in early interactions has rewritten the social script of friendships, as well as for romantic partners. This section, then, discusses two unique

ways that modern friendships intertwine with sexual interaction: *friends-with-benefits relationships* and *back-burner relationships*. Both of these relationships come with a unique form of sexual access. Moreover, we offer an evolutionary explanation for the persistence of each of these relationships.

Friends-With-Benefits Relationships

The interplay of sexual access and friendship is seen most clearly in the notion of a friends-with-benefits relationship (FWBR). Working from the lay definition of a relationship that comes with *no strings attached*, friends with benefits were initially defined as friends who engage in repeated episodes of sexual interaction without the expectation of romantic motivation and/or escalation (Hughes et al. 2005). The no-strings-attached notion suggested that the sexual aspect of an FWBR does not restrict partners' ability to interact (communicatively or sexually) with other individuals. In short, FWBR partners are not supposed to hinder one another's extradyadic interaction in any way.

Given initial definitions as friends who have sex on multiple occasions with no strings attached, early research assumed that all instances of FWBRs were all pretty much the same. After closely reviewing a decade of research, Mongeau et al. (2013) painted a more complex picture. Some FWBR partners tend to shun romantic motivations, while other partners embrace romantic involvement. Some FWBR partners were indeed friends or even prior romantic partners, whereas others were strangers or nodding acquaintances. Based on their alternative reading of the literature, Mongeau et al. (2013) claimed that friends with benefits come in multiple forms that vary in relational and sexual characteristics. Specifically, they described seven types of friends-with-benefits relationships that range from close friends who engage in intercourse (i.e., *true friends*), to couples who meet exclusively to having sex (i.e., *just sex*), and to mutual *sexual fail-safe* with overlapping social networks (i.e., *network opportunism*). What is more, Mongeau and colleagues

reported that FWBRs can lead to romantic relationships (three types of *transition in*: successful, accidental, and failed) or stem from one (*transition out*).

Perhaps the growing popularity of friends with benefits among emerging adults (i.e., individuals aged 18–25) is related to simultaneously enjoying increased independence and desiring sexual experimentation (Teachman 2003). In some ways, the norms and expectations from earlier generations remain in the friends-with-benefits realm. For example, in friends with benefits, the sexual double standard (where recreational sex was seen as positive for men but negative for women) emerges, though in a different form. Repeated casual sex is considered as a performance of status for men and as a desire for relational commitment for women (Impett and Peplau 2003). Despite potential conflicting motivations, it does appear that both men and women prefer to have repeated sex with a trusted friend (Epstein et al. 2009) as opposed to a stranger (i.e., a hookup; Bogle 2008).

The FWBR phenomenon presents a unique set of communicative, relational, and sexual challenges. For example, relationship talk (e.g., *labeling* or rule setting) is typically seen as threatening and something to be avoided in FWBR (Knight 2014). In some ways, this finding parallels the twentieth-century notion that explicit talk about, or performance of, sex in friendships as taboo and damaging. Unlike romantic relationships, however, FWBRs are thought to be so simple that they do not require explicit relationship talk and should, instead, emerge organically. This lack of communication manifests in a number of unique ways in FWBRs. For example, it appears as though the inherent friendship at the center of FWBRs stifles safe-sex practices (Vanderdrift et al. 2012). Still, the growing frequency of FWBRs among young adults implies that these are not major hurdles en route to engaging in this form of relationship. Indeed, FWB partners appear to value their friendships more than they do the sexual benefits that they entail (Lehmiller et al. 2011).

There is also considerable variability between the ways that men and women experience FWBRs.

Consistent with work on dating (e.g., Mongeau et al. 2004), men and women espouse different goals in FWBRs. Not surprisingly, men are more motivated by sexual factors (i.e., desire and report more sex) than are women (Green and Morman 2011), whereas women are more motivated by emotional connection than men (Lehmiller et al. 2011). Moreover, increased sexual contact appears to mitigate depressive symptoms in males, while increasing such symptoms in women (Grello et al. 2006). This suggests that FWBRs are healthier for men than women. Such a conclusion is in line with evolutionary theories that posit men prefer short-term sexual relationships to women's long-term commitment goals (Buss and Schmitt 1993).

Friends-with-benefits relationships can be used as a bridge between platonic friendships and romantic relationships (Owen and Fincham 2012). Such a path, however, needs to be agreed upon by both FWB partners, as feelings of constraint tend to lead to negative relationship appraisals, as well as psychological distress (Owen and Fincham 2011). What is more, mutual relationship agreement may be tricky given the proscription against explicit relational talk. For example, FWBRs vary in their degrees of expressed sexual and romantic desire (Mongeau et al. 2013). As a result, partners often differ in whether and how they enact relational maintenance behaviors (Guerrero and Chavez 2005), including the escalation (or de-escalation) of a relationship. Of course, the nature and meaning associated with such behaviors are contingent upon the goals that each partner has for their relationship.

Finally, FWBRs (in one form or another) are generally considered to be an example of *casual sex*. Although the overriding assumption considering FWBRs is a lack of exclusivity, FWBR types experience varying sexual motivations. As a consequence, it may be that one or both partners engage in an FWBR so they can engage in sexual interactions with multiple partners (Hughes et al. 2005) while at the same time maintaining a close emotional connection with a trusted friend (Epstein et al. 2009). Another way that people in FWBRs may balance these competing desires is through the use of *back-burner* relationships, to be discussed below.

Back-Burner Relationships

A *back burner* can be defined as a person “with whom one is not presently committed, that he or she maintains some degree of communication with, in order to keep or establish the possibility of future romantic and/or sexual involvement” (Dibble et al. 2015, p. 330). In other words, back-burner relationships are backup plans for individuals who are in some way removed from the person in question or already in an alternative relationship. Back-burner relationship appears to be more common than FWBRs, as Dibble et al. report that between 66% and 92% of college students have experienced at least one. One important difference between back burners and FWBRs is the importance that is placed on communication. Although FWBRs are marked by their lack of direct relationship talk (Knight 2014), back-burner relationships revolve entirely around communication, especially mediated communication. For example, computer-based technologies (such as texting, Facebook, and Skype) are commonly used to maintain contact with back burners (Dibble and Drouin 2014).

Another interesting aspect of back-burner relationships is that some partners are unaware that they have been placed on the back burner – primarily due to the abundance of online communication in maintaining such relationships (Dibble and Drouin 2014). As online communication is integral to developing and maintaining friendships (Subrahmanyam and Greenfield 2008) and a breeding ground for various forms of deception (Caspi and Gorsky 2006; Hancock 2007), sexual desire in a back-burner relationship can be disguised as platonic interest and friendship. Similarly, back burners can be hidden from one’s current romantic/sexual partner(s) and vice versa. Thus, back burners allow for the potential for sexual interaction *through* the maintenance of friendship.

Individuals may enter FWBRs and/or back-burner relationships for similar reasons. It may be that people engage in FWBRs to facilitate intimate contact with their back burners. Buss (1995) explains the importance of maintaining multiple potential sexual partners, especially for men. So, too, people may choose to engage in multiple FWBRs and back-burner relationships

in order to establish a larger pool of potential romantic and/or sexual partners. What is more, relationships with low levels of involvement (such as back burners and some FWBR types) carry lower levels of physical, emotional, and psychological expectations (Buunk et al. 2002). This lack of expectations may be why people tend to cast such wide back-burner *nets* – an average of 32 partners per person (Dibble et al. 2015). This strategy tends to oppose other online methods of sexual communication, which are often individually centered (Drouin 2015).

Conclusion

The interplay of friendships and sexual access (and the research literature investigating them) has changed significantly over the past 50 years or so. Whereas sex between friends was once considered fulsome, the notion of friendship has evolved to include the potential for sexual interaction. In addition, sex is now initiated much earlier in relationships than in decades past. Thus, the window for sexual access vis-à-vis friendships has expanded considerably. The role of sex has shifted from an act that consummates a close relationship to one that serves to investigate romantic potential. Future work may document further evolutions of sex in friendships as sexual intimacy becomes more normative in a wider variety of contexts and between a wider variety of partners.

Synonyms

Females as the spoils of war; Sexual access as the reason for going to war; Sexual access during warfare

Definition

Warfare, defined as lethal coalitional violence, is a human universal and may be partially explained as a result of evolved psychological mechanisms in males for increased sexual access to females.

Introduction

J. M. G. van der Dennen described how, at the Fifth Annual Meeting of the Human Behavior and Evolution Society (1993), Leda Cosmides posed the question “Why would anyone be so stupid as to initiate a war?” and then provided the answer: “To get women” (quoted in van der Dennen 1995, p. 327). Although this answer is often rejected out of hand by most social scientists, and modern scholars of war rarely consider sexual access as a motive for warfare, the notion that coalitional violence is waged by men to gain sexual access to women is far from new. Descriptions of success in war leading to increased sexual access to women are found in both ancient texts and ethnographic accounts of people living throughout the world. Such descriptions are so common that Vallacher and Brooks (2014) list “battles for dominance and mating opportunities” among those causes of war that are “self-evident and do not

warrant detailed consideration” (p. 191). Given that increased sexual access to females can potentially increase the reproductive success of males, the hypothesis that sexual access to females is an *evolutionary* reason for the existence of coalitional violence is also not new. van der Dennen (1995) points out that “similar and comparable theories about the influence of sexual competition on the evolution of male behavior have been put forth by Alexander, Borgia, Manson & Wrangham, van den Berghe, Symons, Tiger, E. O. Wilson, Chagnon, and Low” (p. 327; see also Van Vugt 2012; Daly and Wilson 1988; Keeley 1996; Wrangham and Peterson 1996; Tooby and Cosmides 1988). This paper explores some of the evidence relevant to establishing the exact role increased sexual access to women may have played in the evolution of male coalitional violence.

Adaptation vs By-Product Hypotheses on Male Coalitional Violence and Sexual Access

The role increased sexual access to women played in the evolution of male coalitional violence is not settled by the mere fact that males who were successful in male coalitional violence sometimes gained increased sexual access to females. The evolutionary question is whether or not the increased reproductive success sometimes resulting from participating in coalitional violence caused natural selection to favor males who engaged in coalitional violence over those who did not. If this was the case, coalitional violence (and/or one or more of the various evolved mechanisms contributing to coalitional violence) could be considered *adaptations*, whose *function* was an increase in reproductive success through increased sexual access to females (see ► “*Adaptation*” and ► “*By-Product*”). The mere existence of coalitional violence leading to increased sexual access to females would not constitute such evidence because coalitional violence could exist even if it itself was not favored by natural

selection. If this was the case, coalitional violence would be a by-product, or side effect, of mechanisms selected for other purposes. For example, evolved mechanisms for *individual* violence could sometimes be combined with mechanisms for creating cooperative social relationships and lead to coalitional violence. Then, mechanisms designed by natural selection for sexual behavior in low-cost contexts other than coalitional violence could produce the sexual behavior that sometimes occurs in the low-cost contexts following success in coalitional violence.

There are also several reasons why attempts to calculate if the reproductive benefits of male coalitional violence exceed the costs of male coalitional violence are not necessarily definitive in determining if male coalitional violence is an adaptation or by-product. First, as van der Dennen (1995, p. 331) points out, calculating the costs and benefits in modern wars is of little use because “it is almost certainly true that past correlations between a warrior’s behavior and reproductive success no longer hold.” Further, even demonstrating that the potentially high costs of male coalitional violence, ranging from the obvious complete termination of reproductive opportunities as a result of death to disfigurement and to health costs associated with exposure to pathogens, would *usually* outweigh the benefits of such acts in ancestral environments (i.e., the environment of evolutionary adaptedness or EEA) is not conclusive. This is because such evidence does not rule out the possibility that selection favored engaging in male coalitional violence precisely under those limited circumstances when the benefits of the act outweigh the costs. As Van Hoof (1990, p. 50) points out, “if gaining an additional wife, or even additional copulations, is possible, and the risk of dying in any given encounter/skirmish is low, then it could make [evolutionary] sense to go to war” (see Tooby and Cosmides 1988; see also Navarrete and McDonald 2014; Camilleri 2012). Indeed, the best reason for favoring the adaptation hypothesis over the by-product hypothesis would be evidence of design in the form of coalitional violence accomplishing the proposed function with more efficiency, precision, and complexity than could be expected by chance alone.

To help determine if increased sexual access can be considered the function of coalitional violence, examination of evidence related to the following predictions will be integral. The better the evidence fits each of these predictions, the stronger the case is made that increased sexual access to women is the function of male coalitional violence.

Prediction One: Coalitional Violence Has Been Ancient and Widespread

Fry (2009, p. 4) insists “*warfare is not ancient*” (italics in original). If this proclamation is accepted at face value, the hypothesis that increased sexual access to females was the evolutionary function of war (and/or the mechanisms producing war) is falsified. This is because natural selection is a relatively slow process that could not have designed humans to engage in coalitional violence if such violence was restricted to merely the last few centuries or even millennia. There are, however, numerous reasons for not accepting Fry’s proclamation on face value.

The first indication that war is ancient is that although many aspects of modern warfare are neither ancient nor universal, lethal coalitional violence is present in every corner of the globe and has been throughout human history. Thus, if war is defined as lethal coalitional violence, “war, then, is universal” (Gat 2006, p. 9). Further, cultural anthropologists have found coalitional violence to occur among foragers and other societies living in ways that most closely resemble the social environments of our ancestors. Although there is considerable controversy over this evidence, much of which is fueled by mistaken notions that evolutionary explanations imply a form of genetic determinism (see “[Conclusion](#)”), there is evidence of at least sporadic male coalitional violence in foragers in general, and “the anthropological literature on war offers many examples of chronically hostile intergroup relations among hunter-gatherers” (Schaller and Neuberg 2008, p. 404; see also Wrangham and Peterson 1996).

There is also evidence indicating that the universality of coalitional violence has existed for

many generations. For example, “Mythologies abound in recitals of wars and the superhuman deeds of warriors, and in them war holds the chief interest in life” (Gat 2006, p. 1; Scalise Sugiyama 2014). There is also archaeological evidence of coalitional violence (Keeley 1996, 2014; Schaller and Neuberg 2008; LeBlanc 2014), including evidence of Neanderthal violence (Liddle et al. 2012).

Although lethal coalitional violence could have evolved in only one species, the adaptation hypothesis is strengthened by evidence that such violence has also evolved in other species (Wrangham 1999). Evidence of coalitional violence in our nearest living relatives is also consistent with the hypothesis that it existed long enough in our own lineage to have been subject to natural selection. Liddle et al. (2012) also point out that “Some degree of violence has been observed in virtually every known animal population, and the majority of this violence exists in the context of resource competition with one sought-after resource being access to mates” (p. 7). Liddle et al. (2012) also write, “The coalitional violence observed among male chimpanzees is especially noteworthy in that it most closely resembles human warlike behaviors” (p. 8; see also Schaller and Neuberg 2008). Thus, the evidence indicates that coalitional violence was frequent enough over a sufficient span of time that it may have been subject to natural selection, but further evidence of design is required before concluding that the function of such violence was increased sexual access to women.

Prediction Two: Coalitional Violence Will Be Perpetrated by Males

The hypothesis that the function of male coalitional violence is increased sexual access to females obviously generates the prediction that the frequent and ancient forms of coalitional violence have been perpetrated, almost exclusively, by males. In regard to ethnographic evidence, despite the existence of relatively rare participation by females (Keeley 1996), this prediction is met because “Engaging in war, ... is

almost exclusively a male enterprise ...” (Liddle et al. 2012, p. 15; see also Daly and Wilson 1988; Wrangham and Peterson 1996; Navarrete and McDonald 2014, p. 99). The archaeological evidence also supports the conclusion that “... men are both the primary participants and victims of lethal aggression (Keeley 1996)” (Lambert 2012, p. 325). The same pattern is observed in our closest living relatives: “Among the primate species most closely related to human beings, intergroup hostilities involve males more than females” (Schaller and Neuberg 2008, pp. 403–404). A review of aggressive behavior in primate species also suggests that male aggression is strongly linked to intrasexual mating competition (Wrangham and Peterson 1996; Lambert 2012, p. 325).

Further evidence of design might be found in the form of evidence supporting predictions about which men would be most likely to engage in coalitional violence. The adaptation hypothesis predicts that young males around the age of peak competition for mates will be the most likely to engage in coalitional violence. This tendency has been given the name “the young male syndrome” (Wilson and Daly 1985; Daly and Wilson 1988). It is possible to generate even more precise predictions because “While the need for reproductive opportunities would be present among most young males, some males would be more successful in gaining these through warfare” (Petersen 2012, p. 123). This might be true especially for physically strong and aggressive males. This is because, as Petersen (2012) explains, “Ancestral hunter/gatherer bands would most likely not contain more than a dozen adult males and, hence, the fighting ability of each and every individual male would have influenced the probability that the group as a whole prevailed” (p. 124). Consistent with this prediction, but far from conclusive, Petersen (2012) reports that “physical strength shapes modern attitudes about war: stronger males are more supportive of using war as a means of solving international disputes” (p. 124). Petersen points out that this is consistent with previous studies that found “... countries with many young males are particularly likely to engage in deadly warfare” (Petersen 2012, p. 123).

Prediction Three: Male Coalitional Violence Increases Sexual Access to Women

There is no question that success at male coalitional violence sometimes increases sexual access to women, but the question is whether or not male coalitional violence leads to sexual access with a frequency, efficiency, and precision that indicates design by natural selection. Answering this question is complicated by the fact that male coalitional violence may have led to increased sexual access to females in two fundamentally different ways, and one, both, or neither of these may show evidence of design by natural selection. These two forms of access are sometimes divided into those involving “out-group” females, where males gain sexual access to the females associated with the defeated enemy, and those involving “in-group” females, where the wealth and/or status gained by victorious males leads to them being chosen as sexual partners by their own “in-group” females. Such simplistic group concepts are problematic in many ways, and thus it would be more accurate to classify the forms of sexual access resulting from male coalitional violence into the categories of “direct” and “indirect.” Direct forms of sexual access involve a male gaining sexual access without female choice being involved. These forms would include such things as rape, wife capture, forced prostitution, and sexual slavery. Indirect forms of sexual access are those in which female choice is involved and include females choosing males who are successful at coalitional violence as long- or short-term mates. van der Dennen (1995, p. 330) makes this distinction between direct and indirect sexual access when writing “The benefits of warfare to males in preindustrial societies include increased direct access to reproductive females, and increased material resources . . .” (p. 330) which could then be used to indirectly gain sexual access by making the male more likely to be chosen by females. Konner (2015) also distinguishes between the direct and indirect forms of sexual access when describing both the seizing and rape of “women left behind by . . . fallen enemies” and how “war can bring the

reputation and spoils that enable a man to marry back home” (p. 169). Similarly, Navarrete and McDonald (2014) describe how “... the winners of such conflicts may be rewarded with additional territorial and food resources, increased status, and direct acquisition of females from the defeated group” (p. 103; see also Gat 2006; Wrangham and Peterson 1996; Tooby and Cosmides 1988; Konner 2015). Liddle et al. (2012) ask the question: “how does violence translate into mating opportunities?” (p. 11). Their answer reveals that the distinction between direct and indirect sexual access corresponds to the two forms of sexual selection: “It seems that both intrasexual competition and intersexual selection play important roles, in that intrasexual competition between men is often directly related to status or reputation, and women preferentially choose partners of high status, . . .” (p. 11).

There are also various other forms of evidence that human males may be designed to efficiently exploit sexual opportunities following success in male coalitional competition, but it is not clear whether these are designed for direct or indirect access. Testosterone levels are known to increase in athletes after a win and even in a political candidates’ supporters after their candidate has won (see ► “[Dominance, Testosterone, and Cortisol](#)”). Navarrete and McDonald (2014) point out that in a previous study, men were also found to be “more likely to endorse statements supporting war after they had been primed with attractive members of the opposite sex” (p. 104).

It is important to note that both the direct and indirect hypotheses generate predictions about potential female adaptations. The direct access hypothesis generates the prediction that females have evolved various mechanisms to deal with being captured by enemy men. The indirect hypothesis generates the prediction that females have evolved to be sexually attracted to males who are successful in coalitional violence. A focus on female adaptations, combined with the often blurry distinction between the direct and indirect forms of sexual access, draws attention to an important point. While useful, the application of the direct and indirect categories of sexual violence to specific instances of male

coalitional violence must carefully consider the context of a mating to make sure that an act that might appear to be the result of female choice might actually be an example of "... women's need to behave adaptively in the presence of aggressive males, not women's attraction to dominant men" (Graziano et al. 1997, p. 148). With this in mind, examining the evidence that either or both of these forms of access show evidence of design will provide potential support for the premise that sexual access is a primary function of warfare.

Direct Access

There is no doubt that rape has been an all too common aspect of both modern wars and acts of male coalitional violence in band and tribal societies (for overviews see Chagnon 1997; Thornhill and Palmer 2000). Further, Gottschall (2004) points out that "The promise of sexual access to outgroup women has often been identified by anthropologists, ethnographers, and native informants... as a primary instigator of conflict in prestate societies" (Gottschall 2004, p. 130, and sources therein). Similarly, Konner (2015) writes, "Slaughtering men to get their wives and daughters was routine in ancient war, and women were one main reason for war" (p. 163). Also consistent with this hypothesis is the fact that male coalitional violence is often undertaken to prevent other males from gaining sexual access to females (Van Hoof 1990). There is also evidence that this access could have resulted in reproductive success. Camilleri (2012, p. 175) points out that "Recent evidence suggests that pregnancy is just as likely, if not more likely, to result from rape than from consensual sex..."

The frequency of occurrence of direct sexual access and the evidence that it could lead to reproduction are both consistent with the adaptation hypothesis, but they do not in themselves provide definitive evidence of design. Another possible source of such evidence is the specific and precise instructions sometimes given to male soldiers and warriors that appear to maximize the reproductive efficiency of male coalitional violence. For example, Konner (2015) quotes the following from Numbers 31: "Now therefore kill every male

among the little ones, and kill every woman that hath known man by lying with him. But all the women children, that have not known a man by lying with him, keep alive for yourselves" (p. 164). Lerner (1986) also writes, "There is overwhelming historical evidence for the preponderance of the practice of killing or mutilating male prisoners and for the large-scale enslavement and rape of female prisoners" (p. 81).

While such evidence is supportive of the adaptation hypothesis, there are still reasons for considering it not to be definitive. First, there are examples where such precision and efficiency are not found. Keeley (2014) points out that "Indeed, the capture of women, especially young women, is a common but non universal feature of warfare among the non-state societies known to ethnography and has been documented among several prehistoric people" (p.29; see also Keeley 1996). However, Keeley (2014) also points out that "ethnology, history and archaeology document many instances in which nubile women were not kidnapped, either because they were killed along with everyone else or because they were left alive with all survivors" (p. 29). It could also be argued that instructions to keep young female captives alive while killing the other captives imply that the acts of direct sexual access might not occur as efficiently without the instructions, although it is perhaps more plausible to see the instructions as fine-tuning a tendency that would already be present. There are also examples of efforts trying to prevent rape during war, including establishing rules against raping, including the Geneva Convention IV. However, it could be argued that such rules imply the tendency to engage in such acts if they are not prohibited and punished. Also inconsistent with the adaptation hypothesis are the sexual acts during war that cannot lead to reproduction. While it is common knowledge that the majority of sexual assaults are committed by males against females, the reverse does occur and must be accounted for. Complicating the evaluation of the direct access hypothesis even further is the problem of accurately accessing the frequency of rape during war as it is often unreported and even denied.

The frequent reluctance of women and girls to report rape in some circumstances brings up the argument made by Navarrete and McDonald (2014) that, whether or not male coalitional violence is an adaptation, there is evidence that both the male coalitional violence and the accompanying direct sexual access (e.g., rape) “have occurred often enough throughout history to have been an important selection pressure on the psychology of human *females*” (p. 107; emphasis in original; see also Thornhill and Palmer 2000). Scalise Sugiyama (2014) explains this is because “Results suggest that lethal raiding has recurrently imposed fitness costs on women, and that female cognitive design bears reexamination in terms of the motivational and decision-making mechanisms that may have evolved in response to them” (p. 476). Liddle et al. (2012) point out that these adaptations may include not only means of rape avoidance but also decision-making mechanisms to facilitate the “assimilation of females from the defeated group” (pp.8–9).

Indirect Access

It is also possible that indirect sexual access to women is the function, or one of the functions, of male coalitional violence. For example, Campbell (2005) points out that usually “Contemporary men are not directly fighting *about* women . . . Rather, they are fighting for status in relation to other men because in ancestral times this would have translated to increased reproductive success” (p. 634). LeBlanc (2014) points out that, far from this indirect access being limited to only modern societies, in many societies “Warriorhood is a prime avenue to prestige among young men” (p. 88). Similarly, Konner (2015) points out that not only do wars often lead to the capture of women, they also often lead to the attainment of “the means to acquire women-bridewealth to present to a woman’s family” (p. 160). Further, Konner (2015) emphasizes that “every successful warrior who didn’t get killed or maimed was also acquiring something else: reputation” (p. 160). Sometimes the reputation attained through warfare is formalized as a rite of passage: “In many primitive societies, for example, a male was not entitled to full status as a man until he

distinguished himself in warfare, usually by killing an enemy” (Turney-High 1971, p. 161). Further, Camilleri (2012) points out that “Male warriors in traditional societies have higher status, more sexual partners, and more children. . . , suggesting a direct reproductive benefit” (p. 294; Wrangham and Peterson 1996). Despite the overwhelming and varied types of evidence that men often gain status through success in male coalitional violence, there has been great controversy over this topic, largely because of the mistaken notion that it leads to the conclusion that war is the result of some form of genetic determinism that makes such violence inevitable (see “Conclusion”).

Other possible sources of evidence for design related to the indirect sexual access hypothesis are potential female adaptations concerning mate choice. Van Vugt (2012) discusses evidence that “military men have greater sex appeal, especially if they have shown bravery in combat” (p. 224). At the very least, it appears safe to conclude that Westermarck was correct in observing that women “instructively prefer strong and brave men to feeble and cowardly ones. History of Human Marriage cf.” (quoted in Gat 2006, p. 101; see also Scalise Sugiyama 2014).

Conclusion

The available evidence indicates that human male coalitional violence has been relatively frequent, widespread, and ancient. It also appears that such violence frequently led to forms of increased sexual access to females that probably increased the inclusive fitness of the males who were successful in male coalitional violence. Thus, there is no currently available evidence that falsifies the hypothesis that male coalitional violence in humans is an adaptation and that at least one of the functions of such violence was increased sexual access to females. More specifically, the available evidence is consistent with both the hypotheses that natural selection favored males who gained direct sexual access to women through male coalitional violence and males who gained indirect sexual access to women resulting

from the enhanced status and reputation gained through success at male coalitional violence. However, further investigation of both of these hypotheses is still required to provide definitive evidence of adaptations designed by natural selection and the exact characteristics of these adaptations.

Several forms of future research may shed further light on if, and how, humans are designed to engage in, and respond to, male coalitional violence. Further evidence of design for the direct access hypothesis may be found in ethnographic, historical, archaeological, and cross-species studies of the prevalence of female captives being treated differently than male captives. Currently, there are examples where the treatment of female captives meets the predictions of the direct access adaptation hypothesis, but also examples that do not. Further studies of the relationship between male sexual arousal and outcomes of coalitional violence, especially in contrast to male individual violence, could help to evaluate the direct access hypothesis. These studies should be informed by further studies on potential human female adaptations to deal with such situations. The indirect access hypothesis can be further evaluated by future research on how human males respond to success and failure in male coalitional violence, as well as how they respond to cowardice and non-participation by both themselves and others. Even greater insights may be gained by more research on how male participation, or nonparticipation, in coalitional violence influences female choice of long-term and short-term sexual partners.

The successful undertaking of such studies, and the accurate interpretation of their results, will require the avoidance of several of the misunderstandings that still plague research on areas of human behavior, such as violence and sex, strongly tied to moral judgments and political ideologies. The first misunderstanding that must be avoided is the mistake of equating evolutionary explanations with genetic determinism. Not only do evolutionary explanations address the ultimate level of causation of living things, while the influence of genes is part of the proximate level of causation, but all traits (behavioral and otherwise) of phenotypes are the result of a complex

interaction between genes and numerous environmental factors ($G + E = P$). Although the complexity of these interactions continues to be discovered, it has been known for over half a century that when it comes to identifying the interaction of the genetic and environmental factors in the proximate causation of any trait of any living thing, even trying to argue that one is more important than the other is fallacious to the point of being ridiculous (Thornhill and Palmer 2000). Understanding that no trait is determined solely by genes is crucial because when genes are thought to determine behavior, attempts to change behavior through modifications in the environment are seen as doomed to failure. Thus, an evolutionary approach becomes wrongly equated with acceptance of current levels of such acts as coalitional violence and rape.

The second misunderstanding that must be avoided is the naturalistic fallacy. This is the fallacy of drawing the conclusion that an explanation of a behavior *implies* a moral or ethical judgment of a behavior as good or bad or that an explanation *has* to influence a moral judgment. Of course, an individual is free to make the naturalistic fallacy even after they have been told it is a fallacy. That is, an individual is free to include an explanation when formulating a judgment or even use an explanation as the sole reason for their moral judgment. The naturalistic fallacy just means it is a fallacy to hold that an explanation *must* be part of a moral judgment. Wilson et al. (2003) object to this conception of the naturalistic fallacy by arguing that a person can derive a moral judgment from an explanation *if* an ethical premise is added to the explanation. This is a false objection because there is no logical necessity to include the “if” statement (e.g., evolutionary explanation) among the factors contributing to an ethical judgment. Thus, the Wilson et al. (2003) argument is merely that someone *can* include an explanation of a behavior in their ethical judgment of that behavior *if* they choose to do so. This obvious point is irrelevant to the naturalistic fallacy, because the naturalistic fallacy only refers to the fact that no one is logically *obligated* to include an explanation of a behavior in their moral judgment of a behavior. This point is crucial because the

Wilson et al. argument may encourage people to think there is a logical reason that they have to base their moral judgments of a behavior *at least partially* on the evolutionary explanation of that behavior. Such views may retard efforts to increase knowledge about the evolutionary causes of behaviors like rape and male coalitional violence. This may in turn hinder attempts to decrease the occurrence of such behaviors.

Sexual Access Manipulations

Kristen Syme

Washington State University, Vancouver, WA, USA

Synonyms

Definition

Sexual access manipulations in the context of suicide terrorism occur when terror organizations promise metaphysical sexual rewards as a deceptive form of reciprocal altruism or when the sociocultural environment triggers intrasexual competitive behaviors.

Introduction

Some theorists contend that sexual access manipulations provide an evolutionary explanation for suicide terrorism (Kanazawa 2007). Though sexual access manipulations are evidenced in the rhetoric of some political organizations that recruit potential combatants for suicide terror missions (e.g., Al Qaeda, Hamas, Hezbollah), the empirical evidence that sexual access manipulations are the sole motivation to undertake these missions is specious.

Sexual Reward in the Afterlife

When evolutionary theorists discuss sexual access manipulations in relation to suicide terrorism, they are typically referencing promises of sexual rewards in the afterlife (i.e., “72 virgins”). This promise of sexual reward, though deceptive, relies on mechanisms for reciprocal altruism wherein one agent assists in increasing the fitness of

another agent at an initial cost to himself or herself on the assumption that he or she will be repaid in kind at a future time (Trivers 1971). However, Qirko (2009) noted that the religious teaching that martyrs will be rewarded 72 virgins in the afterlife has been played up and exoticized by Western media outlets. Nevertheless, supporters of certain Islamic terror organizations by all accounts appear to sincerely believe in and promote the teaching that martyrs will be awarded sexual access in death.

Intrasexual Competition

A second potential form of sexual access manipulation is the veneration of suicide terrorists as martyrs by local communities. In humans, male reproductive success is tied to social status (Smith 2004), and the promise of glorification through martyrdom could theoretically act on mechanisms that evolved to motivate males to achieve status through intrasexual competition. In species with intrasexual selection, risk-taking through combat improves reproductive success (Wilson and Daly 1985). A review of the literature indicates that one of the major motivations for suicide terrorism is the attainment of a higher status through the vehicles of religious zeal and the belief that such a sacrifice furthers the cause of the wider society. Kruglanski et al. (2009) stated that the sociocultural climate of suicide terrorism often includes: "...[an] ideology whereby a suicide attack is portrayed as an act of heroic sacrifice... lending one's existence and demise an aura of supreme glory (p. 337)."

Limitations of Sexual Access Manipulation Models

There is mixed empirical evidence to support the sexual access manipulation model as an evolutionary explanation for suicide terrorism. In support of the model, belief in the attainment of rewards in the afterlife is amongst the top three motivations for suicide attack among Palestinian

combatants (Hafez 2006). Secondly, the vast majority of suicide terrorists are males in their early to mid-twenties according to. This age and sex bracket is associated with peak risk-taking behavior – a trait associated with status attainment and high reproductive success (Wilson and Daly 1985). Furthermore, the families and communities of suicide attackers often celebrate them as martyrs in death (Hafez 2006). On the other hand, there is no evidence that suicide terrorists have significantly lower status than the populations from which they come in terms of income and education (Berrebi 2003). Though most suicide attackers are young, unmarried men, there is no evidence to suggest that these males are more likely to remain unmarried in later life (Lawson, Jordan, and Magid 2008). Finally, sexual access manipulations in the context of suicide terrorism must entail a self-deception concerning death such that it does not activate cheating detection (Qirko 2009). Though belief in an afterlife is common among humans, the influence of afterlife beliefs in reciprocal exchange is a feature of the model that remains to be tested.

Conclusion

In conclusion, sexual access manipulations appear to factor into the motivation for suicide terrorism. However, the evidence that sexual access manipulations alone can explain willful self-sacrifice in this context is insufficient. Particularly problematic is data suggesting that suicide attackers otherwise, in fact, have access to mates.

Definition

An evolutionary biological perspective on the effects of the environment on multiple psychological, behavioral, and even somatic features of children's development challenges much thinking about human sexual, behavioral, and reproductive development. Rather than treating some environmental conditions and their effects on sex and reproduction as “good” and others as “bad,” it cast such phenomenon in terms of the contextual regulation of reproductive strategies in the service of fitness enhancement.

Introduction

Most research designed to advance understanding of how developmental experiences influence human development is based on a mental-health perspective which presumes that certain environmental influences and developmental outcomes are good (e.g., sensitive parenting/secure attachment) and others bad (e.g., harsh parenting/aggression). A reproductive-strategy perspective, based as it is on life-history theory – an evolutionary-biological approach to development – conceptualizes developmental processes and products rather differently. What are typically

regarded as manifestations of “nonoptimal” development (e.g., insecure attachment, aggression, risk-taking, early sexual debut), evolutionary-minded thinkers cast as alternative tactics for enhancing reproductive fitness under the ecological conditions that give rise to them. An evolutionary perspective is thus appreciative of the benefits of putatively problematic functioning, not just the costs. Life-history-informed research on modern human development, initiated some quarter century ago, has made significant contributions to the field, though many issues merit additional attention.

In the Beginning

More than three decades ago, anthropologists Pat Draper and Henry Harpending reconceptualized how father absence affects psychological and behavioral development. Rejecting traditional psychoanalytic theory and even more contemporary psychological thinking as to why father absence “adversely” affects children’s development, Draper and Harpending (1982) recast such effects in reproductive-fitness terms.

According to Draper and Harpending (1982) father-absent girls develop psychologies and behavior – that is, a “reproductive strategy” – consistent with the expectation that paternal investment in childrearing will not be forthcoming and that pair bonds will not be enduring; this leads them to behave in sexually promiscuous ways. In contrast, girls who grow up in homes in which fathers are present develop to anticipate the opposite – that men can be counted on as partners and parents. In consequence, they defer sexual activity once they reach biological maturity while seeking to establish and maintain enduring, close, heterosexual relationships.

Beyond Father Absence

What was unique to Draper and Harpending’s (1982) argument was the casting of early experience influences within the family in evolutionary terms emphasizing reproductive fitness, parental investment, pair bonds, and, thereby, reproductive strategy (i.e., not mental health). Indeed, their ground-breaking paper stimulated a somewhat-delayed cascade of theoretical developments and

empirical studies on the role of childhood experience in shaping reproductive strategy. Belsky et al. (1991) were the first to build on Draper and Harpending’s (1982) seminal contribution, appreciating that two things were missing from the latter’s analysis: an explanation as to *how* father absence shapes adolescent and adult functioning and an original prediction that would distinguish an evolutionary-developmental – or evo-devo – perspective from more widely embraced ones. In other words, there was reason to wonder whether the introduction of reproductive-strategy thinking into the study of human development represented anything more than old wine in a new bottle.

Considered reflection on this matter led Belsky and associates (1991) to advance an evolutionary theory of socialization linking childhood experience, interpersonal orientation, and reproductive strategy, one that expanded the scope of thinking about environmental influences well beyond father absence. It has come to be known as “psychosocial acceleration theory,” although it is expressly about the regulation – not just acceleration – of psychological, behavioral, sexual, and reproductive development by a variety of contextual conditions and developmental processes.

Central to the theory, based as it was on more general life-history thinking, was the claim that multiple stressful and supportive extrafamilial environmental factors (e.g., poverty) influence family dynamics, most especially parent-child and marital/pair-bond relations. These in turn shape children’s emotional and behavioral development in the first 5–7 years of life, including attachment security, and, thereby, subsequent social development, including sexual/mating behavior, pair bonding, and parenting. In line with Draper and Harpending (1982), Belsky et al. (1991) argued that this complex and environmentally sensitive developmental system – and thus a suite of interrelated phenotypes – evolved as a means of fitting the organism to its anticipated future environment in order to enhance reproductive fitness (i.e., not mental health) – or at least did so in the ancestral environments in which human development evolved.

Central to psychosocial acceleration theory was the view that parent-child processes and, in

particular, attachment security/insecurity mediated the influence of stressors and supports external to the parent-child relationship, such as family economic situation and marital processes, on (a) the child's general trustful-mistrustful outlook on the world, (b) his/her opportunistic-exploitative versus mutually beneficial orientation toward others, and (c) his/her behavior. But what critically distinguished this theory from all others addressing family and other influences on human development, including the thinking of Draper and Harpending (1982), was its prediction regarding environmental influence on rate-of-development. Specifically, developmental experiences and psychological orientations regulate reproductive development by affecting *the timing of puberty* and, thereby, a cascade of processes involving sexual behavior, pair bonding, and parenting.

Thus, accelerated development eventuating in a fast, quantity-oriented reproductive strategy was most likely to emerge in the context of a variety of stressors, including inadequate financial resources and marital discord, which would undermine parental well-being, thereby giving rise to harsh, rejecting, insensitive, and/or inconsistent parenting; such developmental experiences and environmental exposures would then foster in the child an insecure attachment, a mistrustful internal working model, and an opportunistic, advantage-taking interpersonal orientation. And these developments would stimulate earlier pubertal maturation, a younger sexual debut and, eventually, short-term and unstable pair bonds and limited parental investment as individuals sought to bear more children but not care for them intensively. The alternative, slower, quality-oriented developmental trajectory would emerge in response to a supportive rearing environment, characterized by spousal harmony and adequate financial resources. Such intrafamilial conditions, shaped as they would be by extrafamilial ones, would provide the basis for sensitive, supportive, responsive, and positively affectionate styles of mothering and fathering and, thereby, secure attachments, a trusting internal working model and a reciprocally rewarding interpersonal orientation. Collectively, these developments would

delay pubertal maturation and defer the onset of sexual activity, eventually fostering enduring pair bonds and greater parental investment in fewer offspring.

The underlying bio-logic on which psychosocial-acceleration theory was based was consistent with more general life-history thinking. Under conditions of adversity which convey that the world is – and is likely to remain – a risky place and the future is precarious, organisms should accelerate development to insure that they reproduce before succumbing to the undermining effects of their developmental circumstances, including compromised well-being and/or an early death. Whereas the latter would make reproduction impossible, the former could compromise mate value and thus one's ability to bear and raise robust progeny capable of doing the same. In contrast, under supportive conditions, the organism should grow slowly and become reproductively mature later in life so as to incorporate and thus embody the multiple resources to which it would be exposed, be those nutritional, psychological, or behavioral. As a result, the individual would be a more healthy and attractive mate, as well as someone with the skills to take good care of its offspring. Thus, whereas the fast developer might require, or at least once would have, four children to generate, eventually, two grandchildren, this could be accomplished by the slow developer with fewer offspring and ones cared for in a more nurturing manner.

Testing the Puberty Prediction

In a thoughtful critique published alongside the original presentation of psychosocial acceleration theory, Maccoby (1991) argued that it fit males more than females. Empirical evidence reveals just the opposite, however (Belsky 2012). Not only does research indicate that the general lack of prediction of pubertal timing in males is not just a function of measurement challenges (Belsky et al. 2007), but new thinking suggests that female reproductive strategies are more sensitive to familial and ecological conditions, whereas male strategies are more sensitive to peer experiences (Del Giudice et al. 2011; James et al. 2012). Thus, the remaining focus of this contribution is

principally on female reproductive strategies given Belsky et al.'s (1991) original theory-distinguishing puberty prediction. Recent, nonpuberty-oriented, male-specific extensions of the theory, grounded in sexual selection theory and emphasizing the influence of peers, have been advanced and subject to empirical scrutiny (Del Giudice 2009; James et al. 2012).

A comprehensive review of the evidence related to the puberty prediction led Ellis (2004, pp. 935–936) to conclude that “empirical research has provided reasonable, though incomplete” support for Belsky et al.'s (1991) original theorizing. Upon observing the existence of “converging evidence... that greater parent-child warmth and cohesion is (sic) associated with later pubertal development” in females, he insightfully noted that “the proposed accelerating effect of parent-child conflict and coercion on pubertal development is yet to be clearly established.” Subsequent research, including by Ellis himself, has altered the evidentiary landscape. Ellis and Essex (2007) reported that a composite index of family non-supportiveness during the preschool years – which included measures of authoritarian parenting and negative family relationships – was associated with females' advanced adrenarcheal status at age seven and more mature secondary sex characteristics in 5th grade. Additional Ellis research revealed that family disruption and, especially, father's social deviance – considered to be an index of problematic father-daughter relationships – forecast earlier age of menarche (Tither and Ellis 2008). Relatedly, Costello and associates (2007) discovered that maltreated girls reached pubertal maturity 8 months earlier than non-maltreated girls. Belsky and associates (2007, 2010) extended such longitudinal work. Not only did they observe that early maternal harshness predict earlier menarche but, that via this effect, it indirectly fostered greater sexual risk taking in adolescence. Finally, Pesonen and associates (2008) observed, upon taking advantage of a natural experiment, that young Helsinki girls evacuated from their homeland during World War II and sent to live elsewhere reached menarche at a younger age; notably, they also bore more children by late adulthood than members of the

same birth cohort who remained at home, thereby avoiding the trauma of separation from their families.

However noteworthy these (and other) findings, it is imperative to highlight the fact that the accelerating effect of rearing on pubertal timing proves to be modest, in the range of 2–8 months (Ellis 2004). But, critically, this does not preclude the functional importance of such seemingly modest change in sexual maturation given Ellis's (2004, p. 936) insightful observation that “the time from menarche until 50% of (menstrual) cycles are ovulatory is approximately 1 year if menarche occurs before age 12 and 4.5 years if menarcheal age is 13 or older.” To be appreciated as well is that it is certainly possible that female pubertal timing was far more plastic before its dramatic decline over the past 150 years in the Western world and, consequently, far more susceptible to rearing effects (Belsky et al. 1991).

Genetics, Gene-Environment Interaction, and Differential Susceptibility

It is well established that pubertal timing is substantially heritable. This raises the possibility that the rearing effects under consideration are an artifact of genes shared by parents and daughters. Yet when Rowe (2000, p. 165) directly tested this proposition using a genetically informative design, he acknowledged that “the behavioral genetic view gave no knock out punches.” Moreover, even if Mendle and associates (2006) observed – using a children-of-twins' design that controlled for genetic inheritance through the maternal line – that step-father effects on pubertal timing were most likely, even if not certainly, genetically mediated, Tither and Ellis's (2008) work – which relied on a sibling design that controlled for maternal- and paternal-genetic and family influences in their research on biological father – provided support for just the opposite conclusions.

Instead of pitting genetic and environmental effects against one another, as so many are still inclined to do, it appears more productive to adopt the life-history view that there can be *alternative* and *conditional* reproductive strategies (Belsky 2000), with the former more and the latter less

susceptible to contextual regulation. Notably consistent with this differential-susceptibility-to-environmental-influence perspective (Ellis et al. 2011a) are results from three recent studies showing that both an estrogen-receptor gene (Hartman et al. 2015; Manuck et al. 2011) and physiological reactivity (Ellis et al. 2011) can be used to distinguish females whose pubertal development – and perhaps reproductive strategy more generally – is more and less regulated by rearing experiences.

The Distinctive Influence of the Father

Whereas Belsky et al. (1991) purposefully cast the net wider than father absence when it came to delineating developmental experiences and environmental exposures that regulate the development of reproductive strategies – by highlighting the *quality* of parent-child and marital relations and extrafamilial determinants of these – others embrace Draper and Harpending's (1982) original formulation emphasizing fathers' influence: "girls detect and internally encode information *specifically* about the quality of *paternal* investment. . . as a basis of calibrating. . . the timing of pubertal maturation and certain types of sexual behavior" (Ellis 2004, p. 938, emphasis added).

Even if it is the case that some research implicates the influence of fathers on female pubertal development (e.g., Ellis and Essex 2007) and risky sexual behavior (Ellis et al. 2012), it seems notable that Belsky et al. (2007) failed to chronicle any paternal influence on pubertal development – while documenting maternal influence. What is needed ultimately are more studies like Ellis et al. (1999) examining the (unique) effects of one parent while discounting the effects of the other. Needless to say, such research is challenging to undertake given the difficulty in obtaining the involvement of or information on absent fathers and men whose parental investment is especially limited.

Conceptualizing the Environment

Recall that psychosocial acceleration theory highlighted stressful and supportive rearing environments, broadly conceived, arguing that under contextual conditions of risk and uncertainty there

was an inherent bio-logic to accelerating reproductive development. Although Belsky et al. (1991) appreciated that costs associated with accelerated development represented trade-offs geared toward reducing the risk of dying before reaching reproductive age, it was Chisholm (1999) who called especial attention to local mortality rates. These, he argued, were especially informative cues that natural selection had shaped humans to monitor in order to more accurately forecast the future and regulate reproductive development. Certainly consistent with this claim is evidence linking more dangerous rearing environments and shorter life expectancy with younger age of first birth (e.g., Giskevicius et al. 2011; Nettle et al. 2011). What remains unknown, however, is whether these factors relate to pubertal timing or whether pubertal timing mediates effects of these on reproductive functioning.

In an effort to advance thinking about important features of the environment that regulate the development of life histories, Ellis and associates (2009) undertook a cross-species analysis of existing evidence. In so doing, they extended prevailing psychological models of how stress and support shape human development. These evolutionary-minded developmentalists specifically called attention to extrinsic (or uncontrollable) morbidity-mortality (i.e., environmental harshness) and environmental unpredictability (i.e., extent to which conditions fluctuate across individual lifespan). Under harsh environmental conditions, the risk is of dying before reaching reproductive age, thereby making it bio-logical to develop faster, mature earlier, and initiate sexual activity sooner rather than later. Because of challenges to predicting the future under unpredictable environmental conditions, efforts to mitigate risk are less likely to pay off in terms of enhancing reproductive fitness than might otherwise be the case. Parental investment should thus be less than it otherwise would be, thereby stimulating faster offspring development. Although this new framework has yet to inform pubertal-timing research, recent inquiry underscores its utility in forecasting faster life-history strategies in adolescence (Belsky et al. 2012) and young adulthood (Simpson et al. 2012; see also

Nettle et al. 2011). Future work should not only focus on pubertal timing but test this formulation of critical environmental parameters that regulate reproductive strategies against alternative ones.

Further thinking about the influence of environmental unpredictability on human life history led Frankenhuis and Panchanathan (2011) to offer a novel prediction regarding developmental plasticity and, thereby, the development of reproductive strategies: The time before an individual “commits” to a particular developmental pathway should vary depending on the stability of cues that are reproductively informative. When such cues are stable, they provide a seemingly reliable basis for predicting the future; thus, developmental commitment to a conditional adaptive strategy should be made earlier rather than later in life. When such cues prove less reliable, however, the organism should maintain a more “open mind,” deferring developmental commitment to one or another (conditional) reproductive strategy.

Mechanisms of Influence

Upon first advancing psychosocial acceleration theory, Belsky et al. (1991) highlighted the role that the child’s attachment security played in conveying information about risk and uncertainty from the extrafamilial world through the parent-child relationship to the child. Given a great deal of research showing that diverse contextual sources of stress and support influence parenting, longitudinal evidence linking insecure infant-mother attachment at age 15 months with earlier age of menarche (Belsky et al. 2010) becomes especially noteworthy. After all, it is supportive of the view that attachment is one mechanism by which what occurs both in and outside the family becomes “biologically embedded” and regulates reproductive development.

While psychosocial acceleration theory emphasized the first 5–7 years of life as a sensitive period for the contextual regulation of reproductive strategy, Del Giudice (2009) drew on sexual selection theory to highlight the middle-childhood years, contending that this is a period during which the nascent reproductive strategies established in early childhood can be maintained or revised. Of critical importance were peer relations and intrasexual competition, processes, in

fact, that appear to mediate effects of environmental context on reproductive strategies (James et al. 2012). Indeed, the period when the adrenal glands mature and sexual feelings first become evident – adrenarche – is regarded as a “juvenile transition” and “developmental switch point.” One consequence, Del Giudice (2009) theorizes, is the emergence of sex differences in insecure attachments.

Beyond attachment, Chisholm (1999) called attention to time preference as another important psychological mechanism influenced by developmental experiences that regulates and perhaps even characterizes reproductive strategy. From a theoretical standpoint, individuals who grow up in highly risky and uncertain environments should discount the future, preferring smaller payoffs in the present over larger ones later on. Here, of course, payoff refers to the likelihood of reproducing. The fact that children growing up in more economically, socially, and psychologically disadvantaged families have a more difficult time than others waiting to secure a more attractive reward and are more inclined to settle for a lesser one sooner (e.g., Evans and English 2002) would seem consistent with Chisholm’s claim. It remains to be determined, however, whether time preference itself relates to pubertal development or links rearing experience with reproductive functioning.

When it comes to physiological rather than psychological mechanisms of influence, elegant animal work reveals an entire epigenetic and developmental cascade that is strikingly consistent with Belsky et al.’s (1991) original theorizing. Indeed, Cameron and associates (2005) acknowledged just this in reviewing their experimental research showing that that maternal licking and grooming of newborn rat pups, itself influenced by stressful versus supportive contextual conditions, regulates gene expression and, thereby, stress reactivity, rate of sexual maturation, sexual behavior, and eventual parenting.

Conclusion

Although many social and behavioral scientists continue to regard certain psychological,

behavioral, physiological, and somatic developments as “optimal” – including deferring sexual debut, being faithful to a partner, and caring intensively for one’s children – an evolutionary-biological perspective casts many of these and their opposites as alternative means to the same reproductive-fitness-enhancing end. Different developmental processes reflect, ultimately, different strategies that fit different ecological circumstances. This view, of course, stimulated an original theory-distinguishing prediction regarding pubertal timing, one that has garnered a good deal of empirical support. Moreover, it has encouraged further theory development highlighting (a) the critical importance of harshness and unpredictability as core regulatory dimensions of the environment, (b) adrenarche as an important juvenile switch point, and (c) the fact that individuals likely vary in their developmental susceptibility to contextual regulation. Entertaining these new issues simultaneously raises a host of new questions and avenues for inquiry. Consider just the following: Are some individuals susceptible to harshness and/or unpredictability only early in life? Are others susceptible to one or both only later in life? And are some susceptible to both early and later, with still others susceptible to neither across the lifespan? To the extent that these questions get answered in the affirmative, it would go a long way toward explaining why field studies document environmental effects less powerful than traditional socialization theory has long presumed.

Synonyms

[Genital arousal](#); [Sexual response](#); [Subjective arousal](#)

Definition

An emotional state triggered by internal (e.g., fantasy) and/or external (e.g., visual) sexual cues, consisting of interacting components including physiological (particularly genital) changes and subjective experience (Chivers 2005).

Introduction

Sexual arousal is one of several components of the human sexual response cycle. It is characterized by changes in physiology and/or subjective experience, though these facets may not always coincide with each other (Chivers et al. 2010; Janssen 2011; see below). Physiological changes resulting from activation of the sympathetic nervous system include pupil dilation, increased heart rate, and increased respiration rate; these changes, however, are not unique to sexual arousal, therefore researchers focus physiological measurements of sexual arousal on genital changes associated with vasocongestion (Chivers et al. 2013). *Subjective sexual arousal* refers to one's emotional experience of sexual arousal and involves the integration of physiological and psychological responses (Chivers 2005). There is often considerable overlap between subjective sexual arousal and *sexual desire*, a motivational state that directs behavior (reviewed in Janssen 2011); however, most research has, to date, focused on sexual arousal. Common sexual arousal methodologies are outlined below, along with men's and women's sexual arousal patterns.

Measuring Sexual Arousal: Genital Responses

Physiological sexual arousal in both men and women involves changes in *genital vasocongestion*, in which the genital tissues swell because of increased blood flow to the genital region. Genital vasocongestion leads to penile erection in men and engorgement of vulvar, vaginal, and clitoral epithelium and subsequently vaginal lubrication in women. Genital temperature also increases as a result of genital vasocongestion. Thus, the majority of research on physiological sexual arousal involves assessing genital vasocongestion or outcomes related to genital vasocongestion, such as increased genital temperature or vaginal lubrication (reviewed in Chivers et al. 2013). Because genital responses tend to be relatively difficult for participants to alter (whether consciously or not), genital responses are often viewed as a more

objective measure of sexual arousal compared with self-report.

The most commonly used measure of men's genital vasocongestion is the *penile plethysmograph*, which assesses erectile responses. *Circumferential plethysmography* assesses changes in penile circumference. In circumferential plethysmography, a man places either a thin rubber band or metal cuff on the midshaft of his penis; these devices measure mm of change in penile circumference. *Volumetric plethysmography* involves a glass cylinder placed over a man's penis (by a researcher); the cylinder is attached to a pressure transducer, which detects changes in air displacement as a measure of penile volume (reviewed in Chivers et al. 2013).

Women's genital vasocongestion is most commonly assessed using a *vaginal photoplethysmograph*. The vaginal photoplethysmograph is a clear, tampon-shaped probe that contains a light source and light detector. A woman inserts the probe into her vagina; the light within the probe illuminates the vaginal wall and the blood circulating within it, and the amount of back-scattered light detected is an indirect measure of vasocongestion, because the degree to which light reflects varies relative to the amount of blood in the vaginal tissue. The vaginal photoplethysmograph assesses two aspects of vaginal vasocongestion, however, only one of these is specific to sexual stimuli: *Vaginal pulse amplitude* (VPA) is an indicator of dynamic changes in vasocongestion with each heartbeat, with higher amplitudes (measured in mV) indicating greater arousal. Other less commonly used measures for assessing women's genital vasocongestion include the *clitoral photoplethysmograph* (for assessing changes in clitoral bulb blood volume), the *labial photoplethysmograph* (for assessing changes in vasocongestion in the labia minora), and laser Doppler imaging (to assess changes in cutaneous vulvar blood flow; reviewed in Chivers et al. 2013).

Thermographic measures assess changes in genital temperature that result from increased genital blood flow. They include *thermal imaging cameras* used to detect/record changes in the skin's electrochemical energy and *thermistors* or

small temperature gauges that attach to the penis or labia. Participants attach thermistors to their genitals and researchers position thermal imaging cameras for participants. Thermographic measures may be used with both women and men.

Measuring Sexual Arousal: Subjective Sexual Arousal

Subjective sexual arousal typically refers to one's overall feelings of sexual arousal (e.g., "How sexually aroused/turned on do you feel?"), though participants may be asked to report on their perception of their genital sensations (e.g., "Do you feel warmth in your genitals?"; reviewed in Chivers et al. 2010). These aspects of subjective sexual arousal are positively correlated, suggesting that overall feelings of sexual arousal and perception of genital sensations are strongly linked; the extent to which one is influenced by the other is currently unknown (Chivers et al. 2010). Participants may be asked to report their subjective sexual arousal using *discrete* and/or *continuous* responses. *Discrete* responses are given once or repeatedly at different intervals; they are usually given after a stimulus presentation, however, providing pre- and post-stimulus responses allows for assessing change in sexual arousal associated with a sexual stimulus. *Continuous* responses require participants to rate their subjective sexual arousal throughout a stimulus presentation. Participants may respond to questions about their sexual arousal using a variety of methods; the most common methods used today include using a computer keypad to enter discrete responses or move a bar that represents one's arousal, moving a lever or computer mouse with visual or haptic feedback, and verbal reports.

Sexual Arousal Patterns

It may seem intuitive that the physiological and psychological aspects of sexual arousal should occur in a relatively coordinated fashion, with genital responses coinciding with feelings of sexual arousal and perceptions of genital sensations.

Likewise, one might expect both aspects of sexual arousal to occur when one encounters stimuli that match one's sexual interests. Using several of the measures described above, researchers have found that these expected patterns are not always present and highlight the importance of assessing both physiological and subjective aspects of sexual arousal.

Sexual concordance refers to the relationship between genital and subjective sexual arousal (Chivers et al. 2010). On average, there is a consistent gender difference in sexual concordance, with men exhibiting a strong and positive relationship between their genital and subjective sexual arousal (Pearson's $r = 0.66$; Chivers et al. 2010); men may, however, exhibit genital responses in the absence of feelings of sexual arousal and vice versa (reviewed in Janssen 2011). Women's sexual concordance tends to be positive (on average, Pearson's $r = 0.26$; Chivers et al. 2010) and lower than that of men's. Women's sexual concordance tends to be stronger when thermographic measures are used, relative to when vaginal photoplethysmography is used. The relationship between genital and subjective sexual arousal is also more variable in women, regardless of the genital response measured – some women show a strong positive correlation, others show little to no correlation, and some even show a negative relationship (reviewed in Suschinsky et al. 2016).

A related gender difference involves the degree to which genital and subjective sexual responses correspond with self-reported sexual attractions and interests. Men's genital and subjective sexual responses are *category-specific*, meaning that men's sexual responses coincide with their preferred sexual stimulus categories for gender, activities, and age (reviewed in Chivers 2005). Women's subjective responses tend to be category-specific, such that they match with their self-reported sexual interests. Women's genital responses are not always limited to sexual stimuli that match their preferred sexual partners' gender or preferred sexual activities (reviewed in Chivers et al. 2013); women, unlike men, even exhibit significant genital responses to nonpreferred sexual activities and nonhuman sexual stimuli

(reviewed in Chivers et al. 2013). Recent research suggests that *gynephilic women* (i.e., sexually attracted to women) exhibit genital and subjective responses that correspond with their preferred gender, but that exclusively *androphilic women* (i.e., sexually attracted to men only) do not (reviewed in Chivers 2016).

It is unclear why the differences in sexual concordance and category-specificity exist. The differences are unlikely the result of poor measurement – variation in women's sexual concordance is seen across measures of both internal and external genital responses (reviewed in Suschinsky et al. 2016), and the gender difference is not affected by methodological factors such as stimulus characteristics (e.g., male- vs. female-orientated erotica), sample characteristics (e.g., age of the sample), and statistical factors (e.g., type of correlation calculated; Chivers et al. 2010). Likewise, recent research using thermographic measures of genital responses (which allow better cross-sex comparisons than penile plethysmography and vaginal photoplethysmography; Chivers et al. 2013) and other non-genital measures of sexual interest (e.g., viewing time; Chivers et al. 2013; Chivers 2016) reveal a gender difference in specificity of sexual response.

Gender differences in sexual arousal patterns may reflect evolved traits. For example, given the substantial threat of unwanted sex over the course of human evolutionary history, there would have been strong selection pressure on women to either avoid unwanted sex or minimize its costs. The *preparation hypothesis* suggests that any sexual stimulus elicits an automatic genital response (increased vaginal vasocongestion), which then leads to vaginal lubrication to protect women via pain reduction and/or minimizing injury. Currently, there is mixed evidence to support this hypothesis (reviewed in Chivers 2016).

Women's lower sexual concordance may stem from selection pressures, as well. Sexual arousal influences decision-making (e.g., Skakoon-Sparling et al. 2016), potentially leading women to make poor decisions related to potential mates and sexual activities (Suschinsky et al. 2016; Suschinsky et al. 2009). Gender differences in

potential reproductive rates (i.e., the number of offspring an individual can produce, based on the minimum investment required to procreate) have resulted in different sexual strategies for women and men. Women should be more selective regarding their sexual partners to yield a few high quality offspring; men should be less selective and increase the quantity of sexual partners to ensure multiple offspring. Thus, selection may have favored women with lower sexual concordance to facilitate better mate-related decisions in women. High sexual concordance may have been favored in men, to the extent that both feelings of sexual arousal and a physiological response are required for sexual intercourse in men; the subjective feelings of sexual arousal may motivate interest in sexual activity, and a corresponding penile erection is required for penetration (reviewed in Chivers et al. 2010). Further research is required to test this hypothesis.

Conclusion

Sexual arousal is a complex, multifaceted response, and researchers assess multiple aspects of sexual arousal in laboratory settings. Although genital responses are considered to be more objective than self-reports of sexual arousal, physiological responses do not always correspond with subjective feelings of sexual arousal in both women and men. Thus, it is important to consider both physiological and subjective responses for a comprehensive understanding of sexual arousal.

Sexual Assault and Intimate Partner Violence

Paul R. Gladden and Anthony M. Cleator
Department of Psychology, Sociology, and
Criminal Justice, Middle Georgia State
University, Macon, GA, USA

Synonyms

Domestic violence; Interpersonal aggression;
Mate retention; Rape; Sexual abuse; Sexual
coercion

Definitions

Rape can be defined as “copulation resisted” by a victim “unless such resistance would probably result in death or serious injury to the victim or in death or injury to individuals the victim commonly protects.” *Sexual assault* can also include “oral or anal penetration of a man or woman” (Thornhill and Palmer 2000). We use the term *sexual coercion* (SC) broadly to mean the use of force, intimidation, lying, or psychoactive substances to receive or perform sexual acts involving another individual without that individual’s consent and sometimes without their knowledge or explicit awareness of that act (Gladden et al. 2008). *Intimate partner violence* (IPV) is a broad term including acts of stalking as well as physical abuse and violence, psychological abuse, and sexual abuse and/or violence directed toward a romantic or sexual partner (Centers for Disease Control 2008).

Introduction

Sociocultural theorists of both sexual assault and intimate partner violence often ignore and reject (or sometimes vilify) discussion of evolutionary analyses and genetic influences on these behaviors as irrelevant at best (or pernicious and dangerous at worst). However, evolutionary

perspectives often emphasize environmentally contingent adaptations which point to situational and socio-ecological influences interacting with evolved psychological mechanisms. Because all behavior depends on evolved behavioral mechanisms and because evolved mechanisms are adaptively responsive to socio-ecological conditions (e.g., Buss 1991), understanding sexual coercion and intimate partner violence with evolutionary perspectives shouldn’t, in principle, present a threat to the shared goals of (1) an accurate scientific understanding of the phenomena or (2) the moral obligation of trying to gain control over those influences to stamp them out to the degree possible. A complete and accurate scientific understanding of the causes (rather than ideological beliefs about the causes) should be the best potential way to try to control these behaviors. Here we review some of the theory and evidence that account for sexual coercion (SC) and intimate partner violence (IPV) as related phenomena understood from evolutionary perspectives.

Theoretical and Empirical Review

Behavioral Genetics of IPV and Sexual Assault: (Epi)Genetic Differences Matter

There are individual differences in most behavioral traits including sexual coercion and intimate partner violence (IPV). Turkheimer (2000) suggested that the first law of behavioral genetics is that nearly every trait that varies is partially heritable and discussed how best to interpret such empirical findings (see also Polderman et al. 2015). Although evolutionary psychologists have tended to focus on explaining human universals and sex differences, a comprehensive evolutionary understanding of human psychology needs to include explanations for the maintenance of heritable genetic differences correlated with phenotypic psychological differences. Selection acts on reproductive outcomes, influenced by traits that develop *within one individual*, often through complex, epigenetic gene-by-gene and geneXenvironment interactions (Turkheimer 2000). In other words, selection acts on the reproductive results of differences in *intraindividual*

gene-experience interactions, not on the effects of genes alone in a vacuum, somehow miraculously separated from the effects of the environment (Tooby and Cosmides 1992). (Note: *Within each individual* and *intraindividual* are in italics above to distinguish the mechanisms of *individual* development from the sources of variation causing individual differences.) Thus, a scientifically coherent explanation of any complex human behaviors, including IPV and sexual coercion, must consider (1) how genes adaptively respond (e.g., epigenetically) to particular situations and experiences, (2) that “selection regulates how environments shape organisms” (Tooby and Cosmides 1992), and (3) heritable individual differences in behavioral traits rather than just sex-differentiated human universals.

Shared genetic variation within families might at least partially account for the “intergenerational transmission” of IPV. Using a nationally representative sample of American adolescents, Barnes et al. (2013) found that heritable variation accounted for “24% of the variance in hitting one’s partner, 54% of the variance in injuring one’s partner, and 51% of the variance in forcing sexual activity on one’s partner.” The unshared environment accounted for the rest of the variance. As is common in behavioral genetics results, the shared environment explained *none* of the variance in IPV. These findings seem to contradict a within-family social learning account of why IPV consistently runs in families. However, it’s possible that genetic differences between individuals lead some individuals to be more (and others less) likely to develop violent behaviors via social learning. If this were the case, heritable variation would be the correctly identified source of variance in IPV, despite exposure to violence (within and/or outside of families) mechanistically interacting with genes in the development of mechanisms underlying IPV. As Barnes et al. (2013) point out, epigenetic research indicates that “environmental” stimuli affect genetic “switches,” which turn genes “on” and “off.” “To the extent that exposure to IPV in the home environment flips these relevant switches,” trying to identify “genetic” versus “environmental” causes of behavioral variation in IPV is futile

because genes would be causally involved in the “effects of social learning.” From an evolutionary perspective, genes and gene switches are designed to respond to the environment in ways that have been regularly adaptive. This view points to a need for sociocultural influences to be integrated with evolutionary thinking and genetic/epigenetic research in order to identify new predictions about how such socialization interacts with evolved psychological mechanisms.

Some heritable variation is also implicated in whether someone rapes an adult victim (Långström et al. 2015). It is beyond the scope of this entry to do a thorough review of heritability research and its limitations, but the evidence reviewed here implies that genetics contributes something important to the etiology of IPV and SC (however tortuous, indirect, and synergistic those causal routes may be). The relevant point for us concerning the evolutionary hypotheses regarding IPV and SC discussed below is that genetic variation in something or other matters for understanding the etiology of IPV and SC.

Intimate Partner Violence as a Form of Sexually Coercive Mating Effort

As implied in the definition of IPV above, IPV often involves sexual coercion of a partner. Evolutionary psychologists have interpreted IPV, more generally, as a form of sexual coercion wherein perpetrators use violence to guard and retain a mate, restrict their potential choice of another mate, and prevent rivals from trying to poach a mate. For example, Figueredo and McCloskey (1993) interpreted IPV as a sexually coercive mate retention strategy used by competitively disadvantaged males (i.e., relatively low mate value) to secure mates. Rowe et al. (1997) define *mating effort* as the psychological effort used to “obtain and guard short-term mates.” If IPV is a set of mate retention behaviors, it is, thus, a form of mating effort. Consistent with this idea, mating effort is associated with being male, intrasexual competition, sexual coercion (Lalumiere and Quinsey 1996), and delinquency in general (Rowe et al. 1997). If male-perpetrated IPV functions to sexually coerce a female partner, we should expect IPV to effectively prevent rivals

from mate poaching, prevent sexual infidelity or cuckoldry, and prevent partners from defecting from the relationship. We should also expect sexual jealousy to be linked with IPV because men's jealousy is thought to function to prevent infidelity and increase paternity certainty. Jones et al. (2007) found that higher self-reported mating effort (on which men score higher) predicted (1) higher levels of upset in response to imagined sexual infidelity and (2) self-reported "punitive intentions" in response to imagined sexual and emotional infidelity. Figueredo and McCloskey (1993) found a large negative relationship between *quality* of a couple's sexual relationship and male-perpetrated IPV. Both female infidelity and male jealousy were part of the sexual relationship quality variable that strongly predicted IPV.

Some evolutionary hypotheses suggest mate guarding and intimate partner violence will be directed more often toward jealously guarding someone *more* desirable (Buss and Shackelford 1997) because they have more options to leave the relationship partner in favor of a rival. Surprisingly, Figueredo et al. (2001, 2009) found that perceptions of a partner's high mate value predicted *less* spousal abuse perpetrated by both sexes. In other words, when a partner perceived the other partner as having more desirable and attractive traits, they were less likely to abuse them. Figueredo et al. (2001) argued the reason is that there is a correlation between one's own mate value and their partner's mate value (0.50 in their own sample). Therefore, "competitively disadvantaged females" (CDFs) tend to partner with competitively disadvantaged males (CDMs) in long-term relationships. They suggested CDMs perpetrate escalated mate guarding (including IPV) toward a low-quality partner because females, more so than males, can obtain a better quality mate as a *short-term* sexual partner (possibly to capture a rival's genes for her offspring), even if unable to attract the affair partner as a long-term mate. This increases her CDM partner's paternity uncertainty. Partly consistent with this interpretation, the mate retention efforts of relatively "unsexy" men (at risk of infidelity) evidently increase when their partners are most

fertile (Gangestad et al. 2005). Whereas male partners of highly attractive women guard them more *throughout* their ovulatory cycle, partners of less attractive women intensify their mate guarding *only when it matters for preventing impregnation* by another male.

Extra-Pair Copulation and Sperm Competition: Sexually Coercive IPV as an Anti-Cuckoldry Tactic in Men

Goetz and Shackelford (2009) tested the hypothesis that partner rape is an adaptation for sperm competition. According to this view, partner rape by men becomes more likely when a female partner is sexually unfaithful or suspected of being unfaithful – and functions to prevent a male rival from successfully fertilizing one's partner. They found, across two studies, that men's partner-directed sexual coercion was somewhat positively correlated with women's infidelity and suspected infidelity. Men's (nonphysical) controlling behaviors also predicted their partner-directed sexual coercion.

Time spent apart from one's partner increases risk/opportunities for extra-pair copulations. If sexual coercion toward a partner is an anti-cuckoldry tactic toward increasing paternity certainty, we should expect increased interest in copulation with a partner and sexual coercion directed toward a partner when the couple has spent an increased proportion of time apart (a cue to the risk of female infidelity). Shackelford et al. (2007) found that risk of infidelity, as measured by increased proportion of time away from a partner since the couple's last copulation, predicted men's greater "sexual interest in his partner," "distress in response to his partner's sexual rejection," and "sexual persistence in response to his partner's sexual rejection...independent of total time since the couple's last copulation and the man's relationship satisfaction." McKibbin et al. (2011) found that proportion of time spent apart since last in-pair copulation also correlates with male use of sexual coercion toward a partner *but only among men who perceive higher risk of partner infidelity*. McKibbin et al. (2011) note that partner-directed sexual coercion is related to the total proportion of time spent *apart* since last in-pair copulation, not total time since last in-pair

copulation, supporting the sperm competition hypothesis while contradicting an alternative view that partner-directed sexual coercion is the result of general sexual frustration or mating deprivation. Similarly, risk of infidelity correlates with mate retention behaviors, including intrasexual competition tactics such as threatening rivals (Starratt et al. 2007).

If IPV is ultimately about mating competition, as evolutionary theorists hypothesize, we should expect mate retention and intrasexual competition tactics to be used by the same individuals when faced with threats or perceived threats of infidelity. Figueredo et al. (2018) reported that in samples of both sexes, across five countries, interpersonal aggression toward both opposite-sex partners and toward same-sex rivals was positively correlated with each other and with other measures of mating aggression. In other words, measures of IPV, measures of aggression toward one's same sex, and measures specifically created by evolutionary psychologists to measure "mating aggression" (i.e., intrasexual competition, competitor derogation tactics, mate retention, and mate guarding) were loaded upon by a single *interpersonal aggression* factor. Interpersonal aggression toward both sexes was accounted for by the same influences in a model including self-reported "psychopathic and aggressive attitudes" (including high mating effort), short-term mating orientation (sociosexuality), antagonistic social schemata, poor executive functioning, and fast life history strategies. In other words, the same basic model of influences that accounted for IPV accounted for interpersonal aggression directed toward one's own sex as well as toward the opposite sex, suggesting that many individuals committing IPV are *generally* antisocial and aggressive (rather than "specialists" in IPV). Also, since fast life history strategies (described below) are characterized by short-term mating and promiscuity, such individuals are particularly at risk of infidelity (both their partner's and their own) and, thus, might be more likely to exhibit violent jealousy. Taken together, these results support the evolutionary interpretation that much interpersonal violence (directed toward both sexes) is ultimately about mating competition.

Men's Pornography Preferences, Sperm Competition, and Sexual Coercion of a Partner

Since a partner's infidelity is bad for men's paternity certainty and many men desire sexual variety, it is, perhaps, surprising that some studies (Pound 2002; McKibbin et al. 2013) find evidence that pornographic depictions of sexual situations involving one female with multiple males (i.e., high sperm competition situations) are more common than depictions involving one male with multiple females (i.e., low sperm competition situations) (Pound 2002) and that many men may prefer to view those high sperm competition situations (McKibbin et al. 2013; but see Prokop 2015). Kilgallon and Simmons (2005) reported that when men masturbated while viewing images depicting high sperm competition situations, they produced a higher percentage of more motile sperm compared to when masturbating to images depicting low sperm competition situations. These results seem to suggest that some men may become more aroused while viewing high sperm competition situations, including cuckoldry risk depictions. Wright (1994) suggested that mechanisms such as these might make adaptive sense to outcompete rival males' sperm in situations where a partner has copulated with another man. In other words, these findings fit well with findings that men's sexual interest in and sexual coercion of a partner increase when there has been a risk or perceived risk of infidelity (McKibbin et al. 2011; Shackelford et al. 2007; Starratt et al. 2007).

Rape: Adaptation or By-Product?

Thornhill and Palmer (2000) considered whether, over evolutionary time, human rape was reproductively advantageous to some men under some socio-ecological conditions, favoring specific mechanisms for forced copulation, or if human rape is better explained as a maladaptive by-product of other psychological adaptations that evolved for other functions. In other words, they debated whether or not rape is a specifically evolved reproductive tactic. If rape were an evolved reproductive tactic, it must have increased reproductive success regularly for some men under certain socio-ecological

conditions. Consistent with this possibility, it appears that forced copulation is more likely to lead to pregnancy than consensual copulation after controlling for use of oral contraception (Gottschall and Gottschall 2003). Thornhill and Palmer (2000) considered several possibilities for rape-specific adaptations including potential psychological mechanisms for (1) evaluating the vulnerability of victims (e.g., during wartime when unprotected), (2) motivating some men to rape when under conditions where they are deprived of mating opportunities or when lacking sufficient resources to attract desirable mates, (3) evaluating the attractiveness of potential victims differently than consensual partners (e.g., different age preferences for victims at peak fertility), (4) resulting in differences in male sexual arousal in response to depictions of forced sex compared to consensual mating, (5) resulting in differences in sperm counts in rape contexts compared to consensual contexts, and (6) motivating males to rape as a sperm competition/anti-cuckoldry tactic.

In contrast, the maladaptive *by-product hypothesis* of rape proposes that sexual coercion is a maladaptive side effect of selection for (sexually dimorphic) traits important for men's consensual reproductive opportunities: (1) desire for sexual variety without commitment and (2) inclinations toward instrumental aggression (Palmer 1991). The by-product view predicts that sexual coercers will have particularly high levels of consensual sexual activity (as well as unconsensual sexual activity), so the *by-product hypothesis* is supported by findings that sexual coercers report higher levels of mating effort (Lalumière and Quinsey 1996) and sexual experience (Lalumière et al. 1996). The by-product theory shares similar features with the confluence model (Malamuth et al. 1995), which suggests that sexual aggression results from two "paths" that may converge: *hostile masculinity* and *promiscuous and impersonal sex*.

Are Sexually Coercive Men Competitively Disadvantaged, Mate Deprived, Both, or Neither?

Thornhill and Thornhill (1983) hypothesized that sexual assault may be a conditional

(environmentally contingent) adaptation expressed among some men when they are outcompeted for resources and status, which are important for attracting desirable romantic and sexual partners. Consistent with this *competitively disadvantaged male hypothesis*, Figueredo et al. (2000) found that male adolescent sexual offenders were "competitively disadvantaged" (i.e., low mate value), particularly by having psychosocial deficiencies: poor mental abilities, poor social skills, and more psychopathology. According to their interpretation of their evolutionary-developmental model, these psychosocial deficits indirectly led to sexual offending over time as a result of "repeated frustration and failure" in sexual relationships, "leading to an escalation of more and more extreme means of obtaining sexual gratification" (p. 322).

Alternatively, the *mate deprivation hypothesis* suggested deprivation of sexual access *itself* increases likelihood of sexual coercion in some men. The *competitively disadvantaged male (CDM) hypothesis* has been conflated with the *mate deprivation hypothesis*. For example, Lalumière et al. (1996) suggested "if sexually coercive males are disadvantaged in mate competition, they should report a less extensive history of sexual experience (e.g., smaller number of different sexual partners)" (p. 301).

Lalumière et al. (1996) found sexually coercive males report a higher number of sexual partners and a more, not less, extensive sexual history. Similarly, psychopathy, which correlates with sexual coercion of both partners and non-partners (Camilleri and Quinsey 2009b), is associated with higher sociosexuality and mating effort (Figueredo et al. 2018). These findings falsify the mate deprivation hypothesis. Both the *mate deprivation* and *CDM* hypotheses suggest sexually coercive behaviors are conditional adaptations, and it seems like "competitively disadvantaged" in mating competition would imply a likelihood of being deprived of mates and fewer sexual partners, but Figueredo (personal communication) argues that they are divergent theories and that a *CDM* view is consistent with the findings of a more extensive sexual history among sexual coercers. For example, Figueredo et al. (2000) reported that psychosocial deficits directly

predicted higher “noncriminal sexual deviance” on the path to predicting nonsexual general criminality and finally sexual criminality. Their interpretation was that competitive disadvantages “might lead to frustration in the mainstream sexual marketplace and therefore to the selection of deviant avenues of sexual expression.” According to this view, these “deviant expressions,” driven by an “escalation of means of obtaining sexual gratification,” are consistent with a developmentally contingent increase in mating effort (and, perhaps, relaxation of mate standards) and short-term mating tactics *generally*, which predict more sexual activity (including, evidently, non-consensual sexual activity). In other words, a *CDM* mating strategy may be to mate with as many females as possible, regardless of her desirability (favoring quantity over quality). So, the *CDM* hypothesis should not necessarily be conflated with the refuted mate deprivation hypothesis. But, the available evidence doesn’t currently support the *CDM* hypothesis over the maladaptive *by-product hypothesis*, which predicts *generally* higher levels of sexual activity among sexual coercers.

In our view, the currently available evidence that male-perpetrated sexual coercion of partners may function as a sperm competition tactic is stronger than evidence suggestive of specific adaptations for sexual coercion of nonpartners. This raises the possibility that men coercive of partners are *CDMs* since coercion of partners is a form of IPV. Starratt et al. (2008) found that if men perceived their partner as more desirable than themselves *as a long-term partner*, perception of his partner’s infidelity predicted increased use of sexually coercive “commitment manipulation.” If men perceived their partners as roughly equally desirable *as long-term partner*, his partner’s infidelity also predicted higher levels of other sexually coercive tactics. But there was no relationship between perceptions of women’s infidelity and sexually coercive tactics among men who perceived their partner as relatively more desirable than themselves *as a long-term partner*. This seems to contradict the *CDM* hypothesis with respect to partner-directed coercion because we

might expect relatively less desirable males to coerce more desirable female partners. However, in light of Figueredo et al.’s (2001) interpretation of their findings on IPV generally (see above), because *CDFs* tend to pair with *CDMs* as *long-term partners*, a less desirable female partner is often mated with a low desirability male (*relative to rivals*), and she may have many *short-term* opportunities for infidelity, regardless of her *long-term* desirability *relative to her partner*. So, her relative desirability *as a long-term partner* compared to her partner may not be terribly important for testing the *CDM* hypothesis.

Use of Sexual Coercion in Both Sexes

Up to this point, we have mostly considered male-perpetrated sexual coercion and IPV as forms of mating aggression and mate retention. But females report using some forms of sexual coercion too, though not as frequently as males. Camilleri and Quinsey (2009a) reported finding that, unlike in males, interest in partner-directed sexual coercion in females is unrelated to changes in the risk of infidelity. Considering females have maternity certainty, these findings support the anti-cuckoldry risk hypothesis of men’s sexual coercion of a partner. And while female sexual coercion of men may function to capture a particular man’s genes or to force a particular man into long-term paternal investment, a relationship, or as an attempt to extract immediate resources, it cannot function to ensure maternity certainty.

Life History Strategy, Antagonistic Social Strategies, and Sexual Coercion

Life history (LH) theory suggests that individuals developing in unpredictable and uncontrollable conditions (e.g., high extrinsic morbidity and mortality risk, low parental support) will exhibit clusters of “fast” LH strategy traits including low somatic effort, low parental effort, high mating effort, short-term mating orientation (e.g., high quantity of genetically diverse offspring), high risk-taking, and decreased rule governance (Rushton 1985). In contrast, individuals living in safe, stable, and controllable socio-ecological

conditions will exhibit clusters of the opposite pattern of traits (“slow” LH strategy traits).

Figueredo and Jacobs (2010) argued that fast LH strategists develop antagonistic social schemata and interpret the world as a zero-sum game in that they perceive others’ interests as in conflict with theirs and focus on immediate gratification of their own interests (e.g., obtaining and securing a mate). In contrast, slow LH strategists perceive others’ interests as mutually consistent with their own and tend to delay gratification to serve long-term goals, including mutually beneficial altruism and supportive interpersonal and romantic relationships. Thus, a fast LH strategy is more strategically consistent with low self-control (Dunkel et al. 2013), risk-taking, breaking rules, and interpersonal aggression and conflict than a slow LH strategy. These fast LH traits seem consistent with the use of both IPV and sexual coercion.

Using a college student sample including both sexes, Gladden et al. (2008) found that various apparent intercorrelated indicators of slow LH strategy predicted reduced frequencies of sexually coercive behaviors. Slow LH indicators included long-term mating orientation, low psychopathy, and high self-perceived mate value. According to comparisons of path-analytic models, this “protective” slow LH factor fully mediated the relationship between biological sex of participants and frequencies of sexually coercive behaviors. As in the cross-cultural studies on interpersonal aggression discussed earlier (Figueredo et al. 2018), these results were interpreted as suggesting that slow LH strategy inhibits sexual aggression. Consistent with a LH strategy explanation of sexual coercion, Dunkel and Mathes (2011) found that individuals’ (both men’s and women’s) self-reported willingness to use sexually coercive tactics changed when they were asked to imagine different life expectancies (5 months left to live, 5 years left to live, or at least 50 years left to live). Furthermore, fast LH strategy correlated with willingness to use sexual coercion at the shortest and longest imagined life expectancy conditions, and short imagined life expectancy increased willingness to use sexual coercion in individuals that reported a short-term mating orientation. Since

LH theory suggests that developing under short life expectancy conditions will lead to a faster LH strategy and a more short-term mating orientation, these results support a LH perspective on sexual coercion. Using the same approach, Dunkel et al. (2013) found that both reported self-control and general criminal intent also increased when asked to imagine different life expectancies as described above. Furthermore, self-reported LH strategy moderated these imagined behavioral effects such that trait LH strategy was most associated with self-control and criminal intent when imagined life expectancy was short. This suggests that slow LH may be protective factor against general criminality (including sexual coercion and interpersonal aggression).

LH Strategy, Negative Androcentrism, and Mating Aggression

Since fast LH strategies are associated with interest in short-term mating, mating effort, aggression, and psychopathy (Gladden et al. 2008), fast LH strategies appear to be linked with both aspects of the maladaptive *by-product hypothesis* of sexual coercion and, perhaps, both “paths” of the *confluence model* of sexual coercion (Malamuth et al. 1995). The confluence model implicates hostile masculinity and other forms of negative androcentrism (bias against women), along with interest in impersonal sex, in causing sexual coercion. Gladden et al. (2013) found that fast LH directly predicted forms of negative androcentrism *among both sexes* and that fast LH strategies fully mediated between being male and negative androcentrism. So, according to the model, men only expressed higher average levels of hostile attitudes toward women because of average sex differences in various fast LH characteristics. This parallels the findings of Gladden et al. (2008) that fast LH traits fully mediated between being male and sexually coercive behaviors. So a LH explanation of sexual coercion is consistent with the possible influence of negative androcentric attitudes on men’s sexual coercion. But the results also show more hostile attitudes toward women among fast LH women. This was expected because fast LH

strategy individuals should exhibit increased intrasexual competition and antagonistic social attitudes and interactions toward both sexes *generally* (Figueredo and Jacobs 2010). Since women exhibited significant hostile attitudes toward other women, these results seem inconsistent with perspectives suggesting a sociocultural problem found particularly among men. In sum, fast LH strategies are linked with traits theorized to influence sexual coercion (and IPV) including psychopathy, aggression, negative androcentrism, short-mating preferences, low perceived mate value, and low self-control. A LH strategy account of sexual coercion is consistent with sexual coercion as either a specific design feature of an overall LH strategy or as a by-product of a combination of various LH traits that are designed for consensual mating (Gladden et al. 2008).

Conclusion

There are a variety of evolutionary perspectives on IPV and sexual coercion. Some are adaptationist hypotheses, and others suggest these behaviors result as side effects of selection for other traits. But each suggests that IPV and sexual coercion are ultimately linked in some way to mating competition.

Many personality characteristics have been repeatedly identified as correlates of IPV and sexual coercion overlap (e.g., psychopathy, hostile masculinity, mating effort). LH theory is a broad theoretical framework that tries to explain many somewhat interrelated psychological traits. Figueredo et al. (2018) suggest LH theory is an inclusive framework for integrating many seemingly disparate findings about interpersonal aggression and sexual coercion. For example, LH strategies are theoretically and empirically associated in some way with various proposed influences on sexual coercion and IPV. Although LH theory may help as an integrative evolutionary framework to better understand relations among various findings that were not all originally considered from an evolutionary LH theoretical perspective, much more work needs to be done to identify and understand how specific characteristics associated with

an overall LH strategy uniquely lead to the behavioral expression of interpersonal aggression and sexual coercion. Evolutionary perspectives on IPV and sexual coercion have much to gain by considering influences identified by standard social science perspectives and vice versa.

Definition

Sexual behavior may be broadly defined as all behavior motivated by sexual feelings, desires, or gratification, whether reproductive or not. While a lot of this behavior may be understood and predicted from a reproductive, evolutionary framework, the modern context including different forms of contraceptives might render the current behavior nonreproductive. It is important to note that nonreproductive genital stimulation and same-sex sexual behavior are also covered by the definition. An interesting point in the human context is that sexual behavior is necessary to cover nonreproductive intercourse and intercourse outside of estrus, which is rare in other species.

Introduction

The following entry will provide a short introduction to the many facets of human sexual behavior

from an evolutionary perspective. It will start off considering evolutionary theories relevant to the study of sexual behavior, consider reasons and motivation for sexual behavior, and consider different forms of specific sexual behaviors before considering possible effects of culture and ecological context.

Evolutionary Theories of Sexual Behavior

Sexual behavior is one of the areas of psychological research that shows the largest sex differences. This needs explaining and understanding. Given the context of the current entry, the following text will describe how sex differences arise through evolution. Toward the end of the entry, cultural influence on sexual behavior from an evolutionary perspective will also be considered.

Sexual Selection

The major theory for explaining and understanding sex differences is Darwin's (1871) theory of sexual selection, presented in great detail in "The Decent of Man and Selection in Relation to Sex." Sexual selection is selection for traits that promote mating success (Andersson 1994). Such traits include ones that promote attractiveness, like the extravagant visual ornaments of the peacock's tail, the complex song of the nightingale, chemical signals as used by mammals and insects, or other elaborate mating displays. Sexual selection also selects for traits that promote success in intra-sexual competition, either physically, through weaponry or large body size, or behaviorally, through threatening displays or aggressive behavior (Andersson 1994; Darwin 1871).

Behaviorally, intra-sexual conflicts to gain access to mates or resources required to mate can be resolved by low-cost signaling (non-exaggerated conflict behavior) or physical contest (exaggerated conflict). Generally, conflicts are more often resolved by nonphysical means than by physical fighting. Physical conflicts mostly occur when the contestants are similar in size and are typically preceded by a phase of visual and/or vocal aggressive displays. Two main factors settle the outcome of intra-sexual conflict:

resource holding potential and resource value. Resource holding potential is fundamentally physical "power," which is strongly affected by relative body size but which can also be affected by the condition of the contestants (health, nutritional status). Resource value, on the other hand, relates to the potential differential value of the resource for the two contestants. With asymmetries in both resource holding potential (e.g., body size) and resource value (e.g., territory ownership), the outcome of conflicts is less predictable, but resource value sometimes trumps resource holding potential.

Darwin considered sexual selection to act on both sexes in humans; something that he considered not to be the case in any other species. When it comes to other species, Darwin has later been proven wrong: sexual selection can indeed work on both sexes, at the same time or at different times, and with similar or different strength ("mutual sexual selection"; e.g., Amundsen 2000; Clutton-Brock 2009). Today, it is becoming increasingly clear that sexual selection acts on both sexes in a multitude of animal species, including humans.

Social Mating Systems

Animal mating systems are defined by the number of individuals of each sex that constitutes a mating unit (Emlen and Oring 1977). By far the most common mating system is polygyny, in which a single male mates with two or more females. Polygyny is the predominant mating system in a range of animal taxa including mammals and is common in several others, for instance, birds. There are two major forms of polygyny: resource defense polygyny in which the male defends a territory within which several females reside and female defense (harem) polygyny in which the male defends a group of females as such but no particular area (Emlen and Oring 1977). Polygyny can involve long-term relationships with multiple females, including paternal care to multiple clutches, as in several biparental passerine bird species. However, relationships can also be brief, as in lekking birds where copulation is preceded by time-consuming assessment and choice by the female, but with no male involvement post copulation. It is worth noting that, in "polygynous

species,” only a fraction of the males mate with more than one female, whereas many, often most, males are bachelors. An example of such a system is the harem-forming red deer. In some polygynous species the mating skew can be extreme, like in elephant seals where a dominant male can mate with up to 50 females. In such systems, male-male competition can be fierce.

Compared to polygyny, monogamy is relatively rare among animals. It is, however, the predominant social mating system in the majority of birds and occurs in some species belonging to other taxa (e.g., butterflyfishes and certain beetles). Monogamy is relatively rare among mammals but occurs, for instance, in several canids. Humans are unique among primates in (sometimes) practicing monogamy. The common occurrence of social monogamy in birds is related to most birds having altricial young: the offspring have a long period of dependence after hatching during which they are usually tended for by both parents. Hence, monogamy in the only taxon in which it predominates is tightly linked to extensive care by both parents. Social monogamy does not, however, necessarily imply sexual monogamy. On the contrary, the majority of socially monogamous bird species show greater or lesser degrees of sexual infidelity (see below). Moreover, many bird species where the vast majority of breeding units are monogamous also have a low frequency of polygynous trios (e.g., blue tits and bluethroats). In such species, a considerable fraction of the males may try to attract a second mate but only a few succeed. The distinction between monogamous and polygynous species is therefore not strict and the terminology settled by convention on a cutoff maximal fraction of males mated polygynously in “monogamous” species.

There is a debate as to whether humans are inherently monogamous or polygamous. In the world today, there are numerically more monogamous than polygynous relationships. However, what is inherently human cannot be judged on the numerical prevalence today, but must be analyzed through history and across cultures. Through history and measured by the number of (relatively) independent cultures, polygyny is and has been the predominant human mating system.

Further, in many Western countries, there is typically a practice of serial monogamy. Further, as considered below, there is ample evidence of extra-pair copulations in seemingly monogamous mating system cultures. Due to extra-pair copulations, it might be relevant to consider a distinction between social mating systems and genetic mating systems, to some degree, as one does with other species. On the other hand, in some recent studies, the number of offspring due to extra-pair copulations is quite small, but they may vary according to ecological features across evolutionary time.

Apart from polygyny and monogamy, two other mating systems occur in animals: polyandry, in which a female mates with several males, and polygynandry, involving multiple individuals of each sex. Neither of these mating systems are common. They are best documented in birds and in some mammals. Examples of polyandry in birds include several species of phalaropes and jacanas. In these species, males care for the offspring alone, which creates a greater mating skew among females than males, with consequently stronger sexual selection on females. A similar situation occurs in several species of pipefishes in which females deposit their eggs in a “brood pouch” on the belly of the male.

Polygynandry, with several mates of each sex, is best studied in two bird species: the dunnock and Smith’s longspur. Polygynandrous units in dunnocks consist of mostly two to three females that each tend its own clutch but which all have copulated with a similar number of males in the unit. These males contribute to feeding of offspring in the nests of any female with whom they have copulated. Notably, studied dunnock populations include all four types of mating systems: polyandrous trios, monogamous pairs, polygynous units, and polygynandrous units. The dynamics of such systems are fluid, as the interests of the two sexes are in conflict. For instance, monogamously mated females would benefit from a second male mate to help care for her offspring; the male, on the other hand, would benefit from breeding with two females rather than one. This fundamental sexual conflict is crucial for understanding mating systems and their

dynamics: what is beneficial for one sex is normally detrimental for the other.

Polyandry in humans is rare and only found in a few cultures. In general males in this circumstance will be brothers, as predicted by inclusive fitness theory. Other relevant factors to consider, though, are ecological constraints. Some have pointed out that the elder brother might have more access; such competition among siblings would be predicted by evolutionary theory, too.

Mating Competition in Males and Females

In animals including humans, mating success is generally more variable among males than among females. The simple reason is that males have the potential to fertilize a large number of female mates (and consequently produce more offspring). Females can mostly gain genetic benefits by acquiring better mates through extra-pair mating. She may also elicit protection or resources from multiple males due to reduced paternal certainty. In consequence, male reproductive success is largely limited by access to females, whereas females are typically limited by resources (to produce and care for offspring) (Trivers 1972). However, the difference in potential reproductive rate between the two sexes varies greatly among species. In birds, lekking species like the black grouse exemplifies species with a strong mating skew where males have a much higher potential reproductive rate than females (i.e., they can mate many more times per time unit). Emperor penguins, for which extensive care by both the male and the female is essential for reproductive success, represent the other end of the scale, with little difference in reproductive rate between the sexes.

With large differences in potential reproductive rate, as in polygynous species, sexual selection will act predominantly on males (Andersson 1994). This is the more common situation in the animal kingdom and leads to stronger mating competition among males than among females (Emlen and Oring 1977). This situation is termed “conventional sex roles” in evolutionary biology and typically selects for extravagant traits and large body size in males. Conventional sex roles and predominant male mating competition are

often associated with strong sexual size dimorphism (like in elephant seals) or sexual dichromatism (like in pheasants or mallards). In species that are socially monogamous, sexual selection may act with similar strength on the two sexes, resulting in similar ornamentation and mating competition (e.g., many seabirds; reviewed in Amundsen 2000). Finally, in polyandrous species, where the female potential reproductive rate is higher, sexual selection acts more strongly on females and can lead to the evolution of more extravagant ornamentation (Amundsen 2000; Darwin 1871) and mating competition behavior in females than in males (Clutton-Brock 2009). Cases where mating competition is stronger in males than in females are termed “reversed sex roles.” The term can be seen as a reflection of the more common nature of predominant male competition and of a historically stronger focus on sexual selection in males.

Variance in mating success and consequent sexual selection is not only affected by the social mating system but also by the sexual mating system. The sexual mating system may deviate significantly from the social mating system when males and females copulate with nonsocial partners, as what frequently occurs in many animal taxa including birds. Extra-pair sexual behavior has been documented in about 90% of bird species, with on average about 10% of offspring being extra-pair. The extent of extra-pair paternity varies greatly among (and within) species in other taxa as well.

Interspecific Variation in Sexual Selection

The strength of sexual selection can vary between and within species. One major determinant of such variation is the operational sex ratio (OSR), the ratio of males relative to females that are ready to mate at a given point in time and space (Emlen and Oring 1977). The operational sex ratio is determined by the potential reproductive rate of the two sexes and by variation in the adult sex ratio, which can deviate quite significantly from 1:1 in many species. When the operational sex ratio, and hence mating competition among males and females, varies significantly on a temporal (or spatial) scale, sex roles become dynamic

(Forsgren et al. 2004). In such cases, sexual selection may act on both sexes, but not at the same time, as in two-spotted gobies, a small marine fish (Forsgren et al. 2004).

Parental Investment

Most animal species display no parental care at all, but when it exists, it is more commonly performed by females than by males, as in mammals and other species with internal fertilization. Internal fertilization is, however, not always associated with uniparental female care. In birds, which also have internal fertilization (yet not internal care of embryos), both sexes typically provide parental care and often with similar parental investment (Trivers 1972). However, levels of investment by the two sexes are fluid, at any given point of time reflecting a sexual conflict over which sex should pay the highest cost of care. Similarly, the maintenance of biparental care in many bird species may reflect an evolutionary game in which the payoff (the net benefit) of staying for the male is assumed to be greater than the potential payoff from deserting (Maynard Smith 1977).

In fishes, the most common care system is by males only. Female only and biparental care also exist but are less prevalent. Uniparental male care occurs, for instance, in species with external fertilization where females deposit large clutches of eggs on a substrate, with the eggs thereafter tended by the male until hatching (Amundsen 2003). Several hypotheses have been suggested to explain uniparental male care in substrate-brooding fishes. While not completely resolved, male care is likely to reflect different payoff functions for the two sexes.

Costs of Reproduction and Life History Strategies

Parental care is costly (Williams 1966) and may negatively impact survival, future fecundity, future attractiveness, and quality of future offspring. For this reason, the optimal investment of an individual at a given time, age, or state will vary, shaping the life history of animals (Stearns 1992). An animal's life history includes age at first reproduction, whether to reproduce once or

multiple times (semelparity vs. iteroparity), number and size of eggs or offspring at a given breeding event, interval between breeding events, and longevity (Stearns 1992). Life history tactics, including age at first reproduction and investment in current vs. future offspring, may vary within species, including humans. With the exception of alternative reproductive tactics such as "sneaker" or "female mimetic" tactics, interspecific variation in life history traits is typically continuous rather than discrete.

The proximate nature of the cost of reproduction varies between, and to some extent within, species. Proximate costs include negative impacts on condition, health, or the cost of a "time-out" from mating (Parker and Simmons 1996). The opportunity cost of being prevented from mating during periods of care feeds back on sexual selection, via potential reproductive rates and consequent effects on the operational sex ratio (Parker and Simmons 1996).

In Trivers' pioneering work (Trivers 1972), sex differences in parental investment were suggested to mainly reflect the relative investment in each gamete by males and females. However, later work has refined the theory to take into consideration total gamete investment and focus on the relative benefits and gains for the two sexes from parental care (the payoff functions for males and females). These payoff functions may vary widely among and within species, depending on demographic (e.g., the operational sex ratio) and ecological (e.g., when a rich source of food for the young reduces the cost of partial or complete desertion) factors.

Most primates display some form of polygyny, with limited male care apart from group defense, as in gorillas. In this respect, *Homo sapiens* deviate from the other primates. Modern, and in particular Western, human populations typically display biparental care including extensive male care. Biparental care also is widespread in other cultures, but is highly variable in form and extent of care. While male and female care may be of similar form in Western industrialized societies, male and female parental roles are more differentiated in most other extant cultures and also in historical societies (Low 2000). Polygynandry is

maybe overlooked as a typical mating pattern of humans over the life course. Members of both sexes have variable numbers of partners during life, while extra-pair copulations are possible and possibly frequent (Fincham and May 2017), although in Western samples this behavior rarely results in offspring.

Buss and Schmitt (1993) have formulated a specific version of how sexual selection and parental investment may affect human sexual behavior called sexual strategies theory (SST). SST is therefore a species typical constriction of the general theories above, including inherently sex-differentiated features such as lower minimal, but present, paternal investment (only typical in 5% of mammalian species), at least partially hidden estrus, paternal uncertainty, and especially the different mating contexts provided by long-term committed romantic relationships and short-term sexual relations (Buss and Schmitt 1993). SST thus suggests that there will both be effects of mating context and sex for different aspects of sexual behavior and motivation. From the theory it is predicted that both sex and mating context will influence sexual behavior. Relative to women, men will, for example, have more to gain from short-term relations resulting in short-term mating representing a larger component of men's sexual strategies. Certain features like physical attractiveness is expected to be preferred by women to a stronger degree in short-term relationships than in long-term relationships potentially due to reproductive benefits by passing genes related to features of attractiveness to the offspring.

Individual differences from an evolutionary psychology perspective have been given more attention the last few years. Some of these approaches consider the evolution of the Big Five personality traits, whereas others consider fast and slow life history and psychopathology. From a sexual behavior perspective, the most relevant individual difference measure is restricted or unrestricted sociosexual orientation as measured by SOI-R (Penke and Asendorpf 2008). This measures to what degree a person is willing to partake in short-term sexual relations with low intimacy and commitment, including

actual number of short-term partners, positive attitudes to short-term sex, and spontaneous desire and fantasizing about people one meets.

There are individual differences in traits that predict life history-relevant sexual behaviors. Sociosexual orientation differs between those who are restricted and those who are unrestricted in seeking short-term sexual relations. There are stable sex differences in sociosexuality, with men being in general more unrestricted, especially for the desire component. But there are also large individual differences. One controversial suggestion is that there are two mating orientation morphs in the population (short-term vs. long-term), although most SOI data suggest a normal distribution.

Age is another relevant measure of individual difference. Human sexual behavior appears relatively late, due to slow maturation. Moreover, humans have menopause that is rarely observed in other species. Women's fertility and reproductive value are strongly linked to age, with fertility peaking in the early 20s and declining until menopause. Since men seem to have strong preferences for cues of fertility, evolutionary psychologists have investigated how sexual attraction and partner preferences change with age (e.g., Buss 1989) – especially for women's age. As shown below, patterns of sexual behavior in humans wax and wane across the lifespan.

Reasons for Sex?

As the ultimate explanation of sexual activity is to produce offspring, the answer to the question of motivation or reasons for sex might seem given. Many mammalian females are only sexually active during the conceptive phase of the menstrual cycle when offspring can be produced. However, most anthropoid primates are sexually active during nonconceptive phases as well, which suggests that there are other reasons for engaging in sexual intercourse than producing offspring. Motives for such sexual behavior in our close relatives might be to create paternity uncertainty, tension reduction, reconciliation, or exchanging sex for food. Humans also engage in sexual activity in nonconceptual

phases, to a very large degree. Brewis and Meyer (2005) found, for instance, no difference in frequency of sex between different menstrual cycle phases in a sample of about 20,000 women across 13 countries.

However, the proximate reasons or motivations for this kind of nonconceptive sexual behavior have not been investigated until recently. As predicting and understanding sexual behavior need to consider sexual motivation, this lack of studies is surprising, and most previous studies have considered motives for sex in humans to be few and simple, including reproduction, to relieve sexual tension and to experience sexual pleasure. More recent studies suggest that reasons for sex and sexual motivations are much more numerous. Meston and Buss (2007) discovered that there are four major groups of motivations for engaging in sexual intercourse and that these may be subdivided into 13 sub-factors. The four main factors consisted of physical reasons, reasons related to goal attainment, emotional reasons, and insecurity reasons for engaging in intercourse and contained 142 distinct reasons in total (i.e., across the four factors). The reasons are far from few and not as simple as prior research had indicated, ranging from physical pleasure (e.g., "It feels good"), emotional attachment (e.g., "I desired emotional closeness"), gaining something (e.g., "I wanted to be popular"), physical attraction (e.g., "I saw the person naked and could not resist"), and pressure (e.g., "I felt obliged") to relationship attainment (e.g., "I wanted to increase the emotional bond by having sex"). Both personality and individual differences in sexual strategies were linked to different factors of sexual motivation. For instance, among women, agreeableness (Big Five personality traits) was significantly negatively associated with each of the physical, goal attainment, and insecurity factors. This is consistent with previous research suggesting that more disagreeable women were more sexually experienced and more likely to engage in unrestrained sexual behavior than were agreeable women (Meston and Buss 2007). High scorers on SOI also tended to endorse more reasons for having sex than low scorers with the exception of reasons related to love and commitment, which is not surprising as

high scores express favorable attitudes toward casual sex. The factor structure was recently replicated in a Norwegian sample, and the replication utilized sexual strategies theory to predict both sex differences and difference between mating strategies, with findings mostly consistent with the theoretical hypothesis.

Previous studies have found that, relative to women, men tend to initiate sexual activity more often and to be less satisfied with the frequency of sexual activity (Okami and Shackelford 2001; Grøntvedt et al. 2015). However, few studies have investigated which factors influence men and women's initiative for sexual activity in different mating contexts. Considering the impact of multiple predictors for initiative of sexual intercourse, Grøntvedt et al. (2015) found different factors predicting sexual initiative for men and women within both relationship contexts. In long-term relationships women increased initiative taking as a function of the length of the relationship and the compatibility with their partner, as in shared interests and values with partner, whereas, for men, independence in women increased initiative taking. Both sexes increased initiative as a function of the desire component of sociosexuality in a short-term context. Moreover, initiative increased as a function of Meston and Buss' pleasure reasons (i.e., "I was horny"; "I wanted an orgasm") for sex, but only for men.

Specific Types of Sexual Behaviors

The following list of human sexual behaviors is not exhaustive or meant to provide a complete catalogue of all possible types of sexual behaviors. It is meant to illustrate some relevant sexual behaviors and consider them from an evolutionary psychology perspective.

Reproductive Sexual Behavior

A lot of heterosexual sexual behavior, both in short-term and long-term relationships, may be considered from a reproductive perspective. According to Herbenick et al. (2010), findings from a national sample show that incidence of vaginal intercourse last month increases from the

lowest rates in the youngest studied group (14–15 years), 8% reported by adolescent men and 6% reported by adolescent women, with a peak for the age group 25–29 years, 74% for both men and women. Thereafter there is a steady drop to the eldest studied group (+70), 28% and 12%, for men and women, respectively. Interestingly these numbers mirror similar findings (see below) for last month incidence of masturbation, suggesting that this reflects general sexual desire. While intercourse is potentially reproductive, birth control interventions will routinely be used to regulate unwanted pregnancy.

A recent study found that the hormones that make these hormonal contraceptives effective also may influence sexual behavior (Grøntvedt et al. 2016). Thus from a conceptual perspective, it is not always clear whether the behavior has a pair-bonding, extended sexuality foundation, rather than reproductive motivation. Also relevant for is the findings that reproduction is not often the explicit aim for most sexual encounters and behavior (Meston and Buss 2007). Typically, reproduction does not depend on conscious reproductive aims in any species. Reproduction is a consequence of sexual desires, pleasure, and behavior. As such one will see age preferences for slightly older women in men younger than women's peak reproductive age. Further, evolutionary predictions suggest that increasing age will cause reproductive expediting as women get closer to menopause.

Nonreproductive Sexual Behavior

It is typical for humans to engage in non-reproductive sexual behavior. Most non-reproductive sexual behavior is probably heterosexual foreplay followed by intercourse during low risk of conception periods of the cycle and while participants are using contraceptives. In addition, self-stimulation behavior or masturbation would be a human nonreproductive sexual behavior.

Extended Sexuality

Typically, most mammalian species concentrate most sexual behavior to periods of high conception. Intercourse outside of estrus might still have

a small chance of resulting in conception, but while this may be the case there may be a specific function of extended sexuality in humans (Grebe et al. 2013). Extended sexuality may not therefore be an elongation of estrous sexuality; rather it may be shaped within the context of pair-bonding with nondominant males gaining sexual access and paternity assurance through the evolution of extended sexuality. Grebe et al. (2013) found support for this view as coupled women's initiation of sex during the nonconceptive luteal phase was found to be particularly sensitive to their own investment in the current relationship. When controlling for women's own investment, male partner's investment in the relationship negatively covaried with women's initiation of sex during the luteal phase, suggesting that women are particularly sensitive to threats of low investment from partners in ongoing relationships during this phase.

From an evolutionary functional perspective, likelihood of conception is hypothesized to account for differences between estrus and extended sexuality. Physiologically, selection has likely shaped these phases to differ through the effects of reproductive hormones with estradiol peaking mid-cycle. Hence, this might promote fertile-phase sexuality, and progesterone rising during the luteal phase might suppress fertile-phase sexuality. Using data from women in relationships, using hormonal contraceptives, Grøntvedt et al. (2016) found interactions between different amounts of different synthetic hormones and differences in specific relationship qualities on rates of sexual intercourse. More specifically the study found that when women lack loyalty and faithfulness in their relationships, high estradiol and low progesterone activity from contraceptive hormones (similar to the estrus phase of the ovulatory cycle where chances of conception is relatively high) were associated with higher rates of sexual intercourse than were high progesterone and low estradiol levels (similar to the luteal phase where chances of conception is relatively low). But this difference was reversed when women perceived themselves as highly loyal and faithful to their relationships. This suggests that hormonal contraceptives not only mimic physical

effects of natural hormones, but they may affect patterns of women's sexual interests as well.

Masturbation

Masturbation or self-stimulation is a frequent type of human sexual behavior and also found across a large range of species. As would follow from greater male sexual desire, men masturbate more than women. A meta-analysis of 177 sources on sex differences on 21 different measures of sexual attitudes and behaviors found the largest sex difference for masturbation incidence, $d = 0.96$ (Oliver and Hyde 1993). The authors note that there was a small sex difference in attitudes toward masturbation. Herbenick et al. (2010) present data from an American probability sample: they find that men masturbate more than females for all age groups. There is an increased difference from the youngest age group (14–15 years) with 43% last month for adolescent men and 24% last month for adolescent women to the highest monthly incidence of 69% men and 52% women, respectively, for the age group 25–29 years. This is followed by a steady decline until the highest age group (70+) with 28% and 12% for men and women, respectively.

Extra-Pair Sex

The estimate of nonpaternity (children sired by another man than the woman's partner and presumed father) has fallen during the past decades and is currently closer to 1–3% (Larmuseau et al. 2016) but varies between subpopulations. This number may have been higher in our species' relevant evolutionary past, but they are still high enough to act as selection pressures for jealousy and mate guarding.

Infidelity is the most typical form of extra-pair sex. There are inherent problems involved in studying behavior based on deceit and with a motivation for secrecy, and the results must therefore be considered conservative. In a current review Fincham and May (2017) summarize the consensus estimates as follows: 2–4% of spouses engage in sexual infidelity in a year. They further estimate the lifetime prevalence of sexual infidelity to be in the range of 20–25% of all marriages.

There has been an increase in rates of infidelity since the early 1990s. With lower degree of commitment and formalization of the relationship, there seems to be an increase in rates of infidelity. Also there is a positive relationship between infidelity and male sex, previous infidelity behavior, unrestricted sociosexuality, and number of partners prior to the current relationship (Fincham and May 2017).

All forms of extra-pair sex are not infidelity. Obviously polygamous mating systems involve sex with more than one partner, but this will not be addressed further in this entry. Consensual non-monogamy involves both sexual and non-sexual extra-pair relations, including swinging and polyamory. Swinging involves couples meeting up with other couples and swapping partners for sexual relations, where emotional ties are not encouraged. Estimates suggest the incidence of swinging in married couples to be approximately 2%, although most partake in swinging only once. While these numbers may be dated, it is hard to find more recent estimates. Swinger parties including several couples follow specific rules, including rules generally for not allowing non-coupled males and sometimes encouraging single females. Most often couples enter swinging through the initiative of the husband, and the major reason for swinging is sexual variety, consistent with sexual strategies theory. The second most popular motive is excitement and physical pleasure.

Open sexual relationships are a third form of consensual non-monogamy, where one or both partners stay in a committed but sexually non-exclusive relationship and have sex with others. Prevalence is hard to measure and there are a very limited number of investigations. National representative samples of single Americans suggest that one-fifth report, at some time, having been in a consensual non-monogamous relationship.

Sexual Harassment and Coercion

Sexual harassment encompasses unwanted or offensive sexual attention or hostile behaviors that focus on gender. Operationalizations of sexual harassment regularly include sexist jokes,

degrading and obscene sexual comments, and homophobic insults, the spreading of sexual rumors, being shown pictures of nudity, and being asked for sexual favors. Often the use of physical force (coercion) is included in measurements of sexual harassment, but researchers are advised to treat harassment and coercion as separate concepts (Bendixen and Kennair 2017). Being subject to and performing sexual harassment (but not coercion) is commonly reported among high school girls as well as among boys.

Mainstream social science theories strongly alluding to feminist perspectives have explained harassment as male power, paternalism and dominance of women typically reflected in measures of acceptance for sexual violence, gender inequality, and hostility toward women. In contrast, the evolutionary perspective has suggested that the desire for sex, and not paternalism or male power, is the driving force for sexually harassing others (Buss 1996). Several studies of adolescent populations find that casual sex experiences and preferences for uncommitted or unrestricted sex (sociosexuality) predicts being subject to and performing sexual harassment (e.g., Bendixen and Kennair 2017) supporting evolutionary perspectives while competing variables from feminist perspectives have performed less well. In addition, a significant proportion of sexual harassment is same-sex behavior, better explained by the evolutionary perspective through sexual derogation tactics, while opposite-sex harassment appears to be a form of sexual solicitation behavior partly rooted in sociosexuality (Bendixen and Kennair 2017).

Inbreeding Avoidance

As for other species inbreeding will have fitness costs. Human kin detection is necessary for both kin selection-based altruistic behavior and also incest avoidance (Lieberman et al. 2007). Such circuitry may be based on both Westermarck effects (duration of sibling co-residence during childhood) and perinatal association with the individual's biological mother. Lieberman and coworkers have found that moral disgust of incest is tied to specific brain networks.

The Use of and Response to Erotica, Pornography, and Sexual Stimuli

Pornographic material is typically characterized by women and men engaging in casual noncommittal sexual acts devoid of feelings of attachment and love. Compared to hardcore pornography, softcore is less sexually graphic and intrusive, while erotica denotes works of art or literature that deal with sex meant to cause sexual feelings. Following sexual strategies theory, men are expected to be more oriented toward this kind of stimuli and be easier aroused by it. In meta-analytic reviews of research on gender differences in sexuality, the use of pornographic material is more common among men than among women, and men also report more sexual arousal in response to sexual stimuli compared to women. Sex differences were slightly larger for studies using pornographic vs. erotic stimuli. Still, these general patterns of findings are affected by several factors. The sex difference in frequency of porn use among adolescents is particularly large and also varies by type of material (Bendixen and Kennair 2017). Moreover, relative to women, men have preferences for a wider range of pornography and prefer hardcore over softcore pornography. On the other hand, women use pornography more often with a regular sexual partner than men do. Finally, there is a sex difference in the specificity of sexual arousal, with men reporting particularly less arousal by watching other men having sex.

Same-Sex Sexual Behavior

Same-sex sexual behavior is observed in a multitude of species. What is very rare is exclusive same-sex sexual behavior. It is quite likely that this has, especially for women, been quite unusual through evolutionary history, too, as freedom to choose may have been low. From an evolutionary perspective, same-sex sexual behavior is neither a mystery nor a problem; exclusive same-sex behavior would be more difficult to explain. With greater sexual liberalism and an increased focus on sexual orientation as an identity, it is possible that individual preferences are more expressed. There are a great number of possible

combinations of sexual orientation, identity, roles, and behavior. Focusing primarily of same-sex sexual behavior, findings consistently find that more people of both sexes engage in same-sex sexual behavior than identify as bisexual or homosexual (Herbenick et al. 2010). Further, twice as many women as men (12% and 5.8%, respectively, aged 25–44) report any lifetime same-sex contact (Chandra et al. 2011).

Prostitution

Prostitution is defined as the act of engaging in sex for material benefits. It is characterized by being low skilled, labor intensive, well paid, and female – although the numbers of male prostitution especially among young men are higher than many acknowledge. Although it is unclear how many women and men are forced or coerced into prostitution, some people, because of restricted alternatives, choose prostitution over regular jobs (and a partner) because it provides a quick and lucrative source of income. From an evolutionary perspective, prostitution exists because of men's powerful desire for sexual variety, combined with the inability of some men to attract women as mates. Some women and men are able to “pursue a strategy of exploiting men's sexual desires to extract money and other recourses in exchange for sex” (Buss 1996, p. 312). Similar strategies are observed in other species, e.g., in macaques and penguins.

Effects of Culture

Typically, human sexuality and sexual behavior are considered to be influenced by culture and ecological factors. Only a simplistic understanding would consider biology and evolved sex differences and adaptations deterministic. On the other hand, cultural differences will often be a result of evolved mental mechanisms. Culture, including factors such as sexual liberalism, egalitarianism, secularism, etc., is often invoked to explain or predict differences in sexual behaviors, including sex differences in sexual behaviors and preferences. In social role theories, the relevance of biological sex differences is downplayed, and

the observed sex differences are attributed to the effects of the relevant society's gender roles. As such the theory presupposes a largely monomorphic sexual psychology. The effects of context or culture might not always work in making the sexes more similar. Also, other factors might be more influential than gender roles, including parasite load, functional sex ratios, or a specific culture's mating system. One example may be increased paternal investment, which might explain greater sex differences in jealousy responses rather than smaller (Bendixen et al. 2015). On the other hand, for some features of sexual psychology, such as male interest in partner virginity (Buss 1989), sexual liberalism may be associated with less and smaller sex differences.

Beyond culture one might consider different effects of ecological differences. Environmental features such as pathogen prevalence and resource scarcity may influence women's partner choice. According to Thornhill and Fincher (2014), there is support for parasite stress affecting human sexual selection and mating systems; parasite stress is positively associated with women's sexual restrictiveness across nations. Female scarcity has also been suggested to be more important than wealth and parasite load in shifting people between short-term sexual behavior and long-term committed relationship. Scarcity of females in geographic regions predicts a reduced willingness of the population to engage in uncommitted sexual relationships. These effects of the operational sex ratio have recently been confirmed experimentally; with more men than women present, men and women shift toward a more restrictive sociosexuality, while both sexes shift toward a less restrictive sociosexuality in ecologies with more women than men.

Conclusions

Sexual behavior encompasses a wide range of different behaviors. Human sexual behavior varies between cultures given different degrees of sexual liberalism, egalitarianism, and mating systems. But there is also variation within nations

based on age, orientation, and ethnicity, and there might also be geographical and temporal effects of different local operational sex ratios. Further human sexual behavior is influenced by sex and mating context (Buss and Schmitt 1993). The same processes and theories that explain animal sexual behavior are to a large degree the best current predictors cross-culturally of human sexual behavior.

Bluffton, SC, USA

Synonyms

Interpersonal violence; Partner or acquaintance rape; Rape; Reproductive coercion; Sexual harassment; Sexual manipulation

Definition

The manipulation of one's romantic partner into engaging in unwanted sexual acts.

Introduction

Sexual coercion in humans occurs when one partner – often the female – are manipulated, tricked, or influenced in to sexual activity. Methods of sexual or reproductive coercion can take many subtle forms, such as financial withholdings, pay-offs, as well as physical or psychological abuse. In more extreme coercion, alcohol and drugs may be used to decrease the resistance of the targeted individual. Rohypnol and ketamine are among several substances used to sexually coerce women and ultimately lower the social consequence for males who engage in sexual coercion (Crooks and Baur 2014). When a woman refuses to consent via coercion, a mate's efforts may be elevated to include coercion through aggression, threats, physical violence, and rape. Like other sexual assaults, coercion is uninvited, unwelcome and without consent. Interpersonal violence and forced in-pair copulation are other existing variables when sexual coercion takes place, both variables affecting the reproductive health and well-being of women.

Forced In-Pair Copulation

The term *forced in-pair copulation* is used to describe when mates rape romantic partners. Observations of aviates have shown that forced in-pair copulation will occur after an extra pair copulation has occurred (i.e., when the female has mated with a new male), so that the in-pair male's sperm must compete for fertilization (Bailey et al. 1978). Evolutionary research posits that this type of sexual coercion is a response to partner infidelity and sperm competition, as an anti-cuckoldry tactic that reduces the males cost of investment on offspring belonging to another (Goetz 2005; Goetz and Shackelford 2009). While the sperm competition hypothesis has an expanding body of evidence to support existence in humans, critics debate the intensity of the adaptation in humans (Goetz 2005).

Rape is the outcome of unsuccessful coercive tactics of mating. Sexual coercion is often an antecedent to forced in-pair copulation when a male partner rapes an already acquired mate in response to suspicion of infidelity. This behavioral

pattern serves the purpose of sperm competition and control over reproduction (Goetz 2005). It has been estimated that 10–17% of wives have experienced spousal rape (Finkelhor and Yllo 1987). Rape includes different varieties of coercion, and not all coercive behaviors result in rape. The term acquaintance rape distinguishes unwanted sexual activity when individuals know, or are acquainted, with each other. Approximately 90% of rapes qualify as date/acquaintance rape (Crooks and Baur 2014).

Evolutionary Evidence from Animal Research

Observational evidence supports the idea that sexual coercion has roots as an evolved mating strategy (Mc Kibbin 2008), and researchers agree that sexual coercion is a conditional precursory tactic to rape. Scorpionflies (*Panorpa vulgaris*) will engage in rape when coercive tactics have been rejected. Specialized anatomical structures (viz., *notal* organ) provide evidence that coercion and rape exist as conditional mating tactics evolved as adaptations (Thornhill and Palmer 2000).

In Non-human primates, a significant level of aggression and forced copulatory behavior exists as males compete for attention of females in estrus. When female chimpanzees reach sexual maturity, males will compete for opportunities to mate. Lower ranking males will attempt to coerce females away from the group if the alpha male has not yet gained access. Dr. Jane Goodall recorded that when the female is unwilling, “a fair amount of brutality” was demonstrated to coerce the female for mating opportunity (as cited in Buss and Malamuth 1996, p. 234). In this capacity, intrasexual competition serves as sexual coercion of females into submission before rape occurs.

Violence between mates has been documented in animal studies, specifically non-human primates, and male sexual coercion also plays a key role in human mating habits to include interpersonal violence. Female orangutans keep solitary lives away from other females or familial groups who may protect them from forced copulation with uninvited males (Wrangham and Peterson 1996). “Morphs” differentiate the male patterns of behavior associated with their category of physical size. Females prefer to mate with the

larger, slower morphs while smaller morphs have more difficulty acquiring willing mates, and are more likely to engage in rape as a mating strategy. Smaller and faster morphs are more likely than larger orangutans, to employ aggressive, violent, and forceful tactics for gaining mates (Mc Kibbin 2008).

Observers have noted that – in silverback mountain gorillas – infanticide is a selective force that causes them to live in group settings (Buss and Malamuth 1996; Wrangham 1979). Male silverback mountain gorillas are known to protect ‘in-group’ females and infants, which increases the females’ and infants’ probability of survival. Infant offspring from out-group males are usually killed. Infanticide coerces females to mate with in-group males because of the increased survival rates of the offspring.

In some ape species, female coalitions are bonded to protect each other from male aggression. Similar familial and social bonds occur between humans when parents and friends protect female children from would-be (undesirable) suitors. ‘In-group’ members of both humans and primates help to conserve reproductive resources, which ultimately affects the social systems in place. Sexual coercion is expressed through life ending violence in the primate world, either through infanticide or matricide (Buss and Malamuth 1996).

Psychological adaptations occur when coercive behaviors have reproductive success over time. Evolutionary researchers hypothesize that these adaptations are mechanisms that allow men to evaluate potential unwilling mates differently than cooperative mates based on the probability of fertility (Mc Kibbin 2008). Young women of reproductive age are more likely than older women to be victimized and experience sexual coercion and rape, supporting the evolutionary theories of mate fitness (Buss and Malamuth 1996). The same is true within the animal world, as reproductive fitness is essential for a species to survive.

The Feminist Perspective

The feminist standpoint provides interference to research through naturalistic fallacy and faulty

belief in males’ genetic determination (Mc Kibbin 2008). However, it is from supporting evidence within the feminist perspective that evolutionary psychologists come to further examine the power hypothesis of sexual aggression. The power hypothesis, as it relates to sexual aggression, can be understood as the male attempt to control or dominate females with the use of physical force, emotional manipulation, resource provision, or denial which keeps women in a state for fear (Buss and Malamuth 1996). This concept stems from the feminist political position, and has validity within the evolutionary study of coercion to gain sexual access consensually. To fully understand sexual coercion, its origin must be explored to help reduce the behavior and the negative consequences that stem from it. Evolutionary psychologists study ‘what is’ and not necessarily ‘what should be’ and from this perspective, coercion and rape are conditional tactics in the mating process. Not all males are prone to become rapists and evolutionary psychology does not attempt to explain rape as a genetically inherited trait, rather an adaptation in response to environmental demands to gain partners at low investment. No ethical research justifies the existence of sexual violence, and study of coercion, rape, harassment and forced in-pair copulation is meant to better understand the origins of significant social problems in tandem with feminist and sociological perspectives (Mc Kibbin 2008).

Types of Men Who Sexually Coerce and Rape

Shields and Shields (1983) reported that one-third of men said they would conditionally use rape as a mating strategy, and that many men also admitted to having coercive fantasies (Mc Kibbin 2008). Eighty-two percent of male college students report having used coercion as a method to gain sexual access, and 21% of males report using physical coercion. One-third of men admitted that, under certain conditions, they would rape (Mc Kibbin 2008). While most men are able to commit rape, there are some unique types of men who may be more likely to rape, and of those men some of these psychological adaptations make them more likely to seek out victims using coercion.

Researchers have identified five potential psychopathological personalities that are more likely to exercise manipulation and violence in gaining sexual access to females. Of these five personality types, there are three which are more likely to engage in coercion. *Opportunistic rapists* will seek out women who seem receptive, but will have a lower possibility of retaliation from the victim or her 'in-group.' He may use coercive methods, such as drugs or alcohol, to seek out low-investment partners to lower the cost or likelihood of being caught in the act of rape. *High mating effort males* will also seek low-investment partners and use coercion to gain sexual access, but these men are noted as having lower fluctuating facial asymmetry (i.e., higher in physical attractiveness), hold themselves in high esteem, and are sexually experienced. *Partner rapists* are perhaps the most frequent to engage in sexual coercion, with interpersonal violence and forced in-pair copulation as contributing variables (Mc Kibbin 2008).

Partnered males will use coercive language in the form of threats, reminders, and persuasion to encourage their mates to have sex. Recent research has discovered evidence of a link between interpersonal violence (IPV) and more subtle methods of coercion that negatively impact the overall health and reproductive consequences of women. The connections between IPV and sexual coercion explain the increased risks associated with unintended pregnancies and women's reproductive health. Reproductively coercive behavior is defined as the use of pressure or influence that compels a woman to abandon her reproductive rights, through manipulation, intimidation, threats, and/or actual acts of violence (Miller and Silverman 2010). Twenty to 45% of teenage and adult women report having been coerced into sexual activity (Crooks and Baur 2014).

Conclusion

Evolutionary psychologists look to explain sexual coercion as a method of mate retention when the female is suspected of infidelity. Furthermore, coercion provides an anti-cuckoldry tactic for males to

protect their investment of resources (Goetz and Shackelford 2009). It is most important to understand that coercion under certain circumstance is not only non-consensual, but against the will or choice of another. In this light, sexual coercion is a side effect or response to sperm competition and women's infidelity. Reports from those who have been raped or abused by their partner usually connect sexual coercion with violence. In fact, abused women are more likely to be raped, physical assaulted, and even murdered by their abusive partner if they attempt to defect from the relationship (Mc Kibbin 2008; Thornhill and Palmer 2000). While this is one hypothesis that explains the cause of sexual coercion, evolutionary perspectives also acknowledge the possibility of an inverse relationship that female infidelity may be a response to sexual coercion (Goetz 2005).

Sexual activity in the animal world is widely studied and has applications within human sexual experiences including those associated with sexual coercion. Evidence in the mating habits of several different animal species, including non-primates (e.g., birds) and non-human primates (e.g., orangutans, chimpanzees, and gorillas), supports evolutionary theories of human sexual behaviors, including mate seeking and mate retention via aggression, sperm competition, and anti-cuckoldry tactics. Parental investment and social coalitions assist young females' resistance to, and protection from, coercion. The role of infidelity is a predictor of male sexual coercion to reduce male cuckoldry, and coercion serves to express dominance and power within a relationship while also increasing the male's chances of reproducing. Although scientific evidence points to sexual coercion being an adaptive reproductive strategy, it must be noted that this behavior is not condoned by evolutionary scientists. Understanding the cause and reasons for sexually coercive behavior may also help decrease, and eventually eliminate, these behaviors in the future.

Definition

The summary term *sexual aggression* (also sexual violence) encompasses sexual activities, for example, sexual intercourse, oral sex, and sexual touching, which are imposed on another person against her or his will. It comprises different coercive strategies, such as the use or threat of physical force, the exploitation of the victim's incapacitated state (e.g., due to alcohol or drugs), or verbal pressure. More specifically, *sexual coercion* refers to penetrative sexual contacts through verbal pressure, whereas *rape* involves sexual intercourse or other forms of sexual penetration through physical force or the exploitation of the victim's incapacitated state, for instance, through alcohol or drugs (cf., Koss et al. 2007). Definitions in the legal context can, however, differ from these research definitions, particularly regarding what specific sexual acts and coercive strategies constitute rape or other sexual offences.

Introduction

Sexual aggression is a severe social and health problem in all countries around the world, entailing numerous adverse effects on victims' health and well-being. The present article reviews the current state of the art of measuring sexual aggression, including its challenges, prevalence rates of women and men, and factors that have been linked to a higher probability of becoming a victim or a perpetrator. Finally, consequences for physical and psychological health are described.

Measurement

Sexual aggression can be assessed from two different perspectives – from the side of the victim, referring to *sexual victimization*, and from the side of the perpetrator, referring to *sexual aggression perpetration*. The precise measurement of sexual aggression victimization and perpetration constitutes a major challenge given the topic's sensitive nature. As it is considered a taboo topic in many countries worldwide, this may preclude the disclosure of such incidents. However, not only

Sexual Coercion and Rape

Synonyms

Sexual aggression; Sexual assault; Sexual violence

social challenges are linked to the measurement but also conceptual and methodological issues arise. Particularly, the phrasing of items is crucial for the detection of sexual aggression. Broad questions – such as “Have you been raped?” – may contribute that responses are affected by stereotypical notions of sexual aggression (e.g., rape is primarily committed by a stranger in a dark lonesome place), which in turn may result in an underdetection (see Cook et al. 2011, for an overview). To overcome this bias, the current “gold standard” for the assessment of sexual aggression is using behaviorally specific items, describing an incident in graphic language without mentioning the word rape. A validated and commonly used instrument is the Sexual Experiences Survey (SES; Koss et al. 2007) which crosses sexual acts (e.g., fondling, oral sex) with coercive strategies (e.g., use of physical force, verbal pressure). Different categories, ranging in their severity from no victimization/perpetration to rape, can be derived based upon the reported incidents. Another validated instrument is the Sexual Aggression and Victimization Scale (SAV-S; Krahé and Berger 2013). Similar to the SES, it assesses the coercive strategy and type of sexual activity but allows, unlike the SES, a cross-classification with the relationship between the victim and the perpetrator.

The Scale of Sexual Aggression

The two major sources to estimate the scale of sexual aggression are crime statistics and representative surveys. Crime statistics typically reveal the annual number of reported incidents to law enforcement agencies. Although these numbers provide a first insight into the scale of sexual aggression in a country, there is broad consensus that these statistics only reveal a minority of the cases. In addition, there is a great variation of legal definitions across countries, impeding comparison of prevalence rates. To get a better estimate of the scale, surveys with representative samples are used. In the United States, the National Intimate Partner and Sexual Violence Survey (NISVS) is an ongoing, representative victimization survey. According to data from 2015, 21.3% of women and 2.6% of men reported attempted or

completed rape at some time in their life, defined as vaginal, oral, or anal penetration against the person’s will through the use or threat of physical force or the exploitation of the victim’s incapacitated state (e.g., through alcohol or drugs). Sexual coercion, referring in this survey to unwanted vaginal, oral, or anal penetration through non-physical pressure, was reported by 16.0% of women and 9.6% of men (Smith et al. 2018).

A large body of research has also examined sexual aggression among college students. The so far largest study on sexual victimization was the AAU Campus Climate Survey on Sexual Assault and Sexual Misconduct which included 27 US higher education institutions, with 150,072 students participating (Cantor et al. 2017). In this survey, 18.1% of women and 4.2% of men reported experiences of completed penetration or sexual touch through incapacitation or the use of physical force since entering college. Generally, prevalence rates of sexual victimization have been found to be higher for women compared to men, whereas perpetration rates were higher for men than for women. However, in recent years, substantial rates of male victimization and female perpetration have been revealed in some countries (e.g., Krahé et al. 2015). Although the stereotypic rape script involves a perpetrator who is a stranger, there is broad evidence that most victims have been assaulted by someone they knew, often by their current or former partner (Krahé et al. 2015).

Risk and Vulnerability Factors

For explaining sexual aggression, studies focus under what circumstances experiencing or engaging in sexual aggression is more likely. In this line of research, risk factors, which are factors that predict an increased probability of engaging in sexual aggression, and vulnerability factors, which are factors that predict an increased probability of experiencing sexual victimization, are examined. It is important to point out that studying vulnerability factors does not imply any responsibility of the victim or that she/he is to blame for the incident. Instead, the goal of this line of research is to identify conditions or

situations which may make a person more vulnerable to sexual victimization. This knowledge may in turn be used for intervention programs to prevent sexual victimization. Comprehensive reviews synthesizing past research were conducted by Tharp et al. (2013) on risk factors of sexual aggression perpetration and by Ullman and Najdowski (2011) on vulnerability factors of sexual victimization. Tables 1 and 2 present a summary of the respective factors. Particularly, childhood maltreatment, prior sexual victimization, and having many sexual partners have been shown to be both risk and vulnerability factors of sexual aggression.

Consequences

Sexual victimization often results in both immediate and long-term negative consequences for physical, psychological, and behavioral health. As comprehensively summarized by Martin et al. (2011), sexual victimization of women is associated with a higher likelihood of different psychological problems, including anxiety, depression, posttraumatic stress disorder (PTSD), and suicide ideation and attempts. In addition, physical health may be affected, including injuries, gynecologic/reproductive health problems, functional limitations, sleep problems, headaches, gastrointestinal problems, and even death. Beyond adverse effects on psychological and physical health, sexual victimization may also result in high-risk health behaviors, such as unsafe sex behaviors and the use of alcohol, drugs, and/or tobacco. Because most research has been conducted with female victims, to date, little is known about adverse effects on male victims. However, the limited evidence for men also suggests that sexual victimization can have notable negative consequences for them (see Peterson et al. 2011, for a review).

Conclusions

Sexual coercion and rape are severe public health issues worldwide. In particular, high victimization rates were revealed for women. Against

Sexual Coercion and Rape, Table 1 Risk factors of sexual aggression perpetration. (Based on Tharp et al. 2013)

Prior victimization history	Sexual, physical, or emotional abuse in childhood Childhood maltreatment Sexual victimization in adolescence or adulthood
Prior perpetration history	Prior sexual aggression perpetration
Family dynamics	Family conflicts Exposure to parental violence Quality of the relationship between child and parents
Partner dynamics	Relationship conflict Avoidance and controlling behaviors Casual relationship status
Sexuality-related cognitions	Sex fantasies
Attitudes	Willingness to engage in sexual aggression Victim blaming Rape myth acceptance Hostility toward women Adherence to traditional gender roles Hypermasculinity Acceptance of violence
Behavior	Fraternity membership Sports participation Gang membership
Sexual risk-taking behaviors	Having many sexual partners Impersonal sex Early sexual initiation Pornography use Sex drive Sexual risk taking
Peer attitudes/behavior	Peer pressure for sex Approval for forced sex by peers Peer sexual aggression perpetration
Risk perception	Failures to interpret cues
Mental health	Delinquency/conduct disorder Suicide attempts Empathic deficits

stereotypical expectations, research has shown that men may also experience sexual aggression and women may be perpetrators as well. Due to the adverse effects of sexual aggression on victims' health and well-being, a broad implementation of prevention programs is needed in the future.

Sexual Coercion and Rape, Table 2 Vulnerability factors of sexual victimization. (Based on Ullman and Najdowski 2011)

Prior victimization history	Sexual, physical, or emotional abuse in childhood or adolescence Sexual victimization in adulthood History of relationship conflict
Trauma history	History of stressors or traumas
Family dynamics	Running away from home Having a mother who had been arrested or who was unavailable because of emotional problems, medical conditions, or alcohol/drug use problems Low paternal care/warmth
Attitudes	Liberal sexual attitudes Rape-supportive attitudes
Sexual risk-taking behaviors	Having many sexual partners
Risk perception	Failures to perceive risk or detect danger cues
Mental health	Intellectual disabilities Psychological disorders (e.g., schizophrenia, depression) Chronic mental health problems Psychological distress as a consequence of prior sexual assault
Alcohol and drug use/abuse	Heavy alcohol use Drug use
Demographics	Being female Being young Being an ethnic minority Being unmarried or separated Low education Low income Living away from home Living in a shelter or being homeless

Sexual Coercion and Violence

Paulina Tomaszewska and Isabell Schuster
University of Potsdam, Potsdam, Germany

Synonyms

Aggression; Sexual aggression; Sexual assault; Sexual violence

Definition

According to the World Health Organization (WHO; Krug et al. 2002), violence, considered as a leading public health problem, is a broad term divided into self-directed, interpersonal, and collective violence of which, except for the self-directed type, all of them can be physical, sexual, psychological, or involving deprivation or neglect. Therefore, the term *violence* includes the term *sexual coercion*. Apart from the broad definition provided by the WHO, other disciplines are trying to narrow down this phenomenon to better understand it. For example, social psychology conceptualizes *violence* as “behaviors carried out with the intention of causing serious harm that involve the use or threat of physical force, such as hitting someone over the head, or – in the ultimate form – taking another person’s life” (Krahé 2013, p. 12). *Coercion* is defined as a form of an instrumental aggression “[...] with the intention of imposing harm on another person or forcing compliance” (Tedeschi and Felson 1994, as cited in Krahé 2013, p. 12). The term *sexual* refers to the nature of the behavior, for example, someone is coerced (through physical force or threat, verbal or other type of influence) to a specific sexual activity (see ► “Sexual Coercion and Rape”). Finally, according to social psychology, both sexual coercion and violence are part of a broader term of *aggression*, which is defined as “any form of behavior directed toward the goal of harming or injuring another living being who is motivated to avoid such treatment” (Baron and Richardson 1994, p. 7). In the further course of this chapter,

we refer to the narrower definition of sexual coercion and violence provided by social psychology and concentrate on adulthood rather than on childhood.

Introduction

Although sexual coercion and violence are different forms of harm, *sexual* and *physical*, and can be considered separately, this contribution focuses on the association between the two. In this article, we will look at the measurement of sexual and physical forms of violence, related problems, their prevalence, and factors contributing to their co-occurrence.

Measuring Sexual and Physical Violence

Because of the sensitive nature of this topic, for those who experience sexual and/or physical harm, and the socially undesirable or even the penal nature for those who commit it, the accurate recording of sexual and physical violence is very challenging. Criminal statistics, representative victimization studies, and research studies are the main data sources for different forms of sexual and physical violence. For example, legal agencies record *crime statistics* based on countries’ legal definition, such as the Federal Bureau of Investigation (FBI) in the United States, the National Crime Agency (NCA) in the United Kingdom, or Bundeskriminalamt (BKA) in Germany. *Representative victimization studies*, for example, the National Crime Victimization Survey (NCVS) in the United States or the Crime Survey for England and Wales (CSEW) provide annual crime statistics based on the national legal definition of the respective crimes. *Research studies* mostly adopt a definition that goes beyond the legal one, which is why the scope in legal terms cannot be assessed. In research, a widely used instrument for collecting data on sexual and physical violence toward an intimate partner is the Revised Conflict Tactics Scales (CTS2) from Straus et al. (1996). This scale measures physical violence, presenting participants with a list of

several actions, both minor (e.g., “slapped partner,” “threw something at partner that could hurt”) and severe (e.g., “slammed partner against a wall,” “kicked partner”). A parallel version addresses acts of sexual harm, again both minor (“insisted on sex,” “insisted on sex without condom”) and severe (“used force to make partner have sex,” “used force to make partner have anal sex”). Participants are asked to respond to the respective items from both victim and perpetrator perspectives. Regarding sexual coercion (also sexual violence or aggression), several other instruments have been developed in the last years. These are described in the section ► [“Sexual Coercion and Rape”](#). In addition, an extensive compendium of assessment tools for measuring sexual and physical violence from the victim and perpetrator perspectives is provided by the Centers for Disease Control and Prevention (CDC; Thompson et al. 2006).

Given the great heterogeneity of definitions, direct comparisons of information from different sources are often difficult. However, having broader definitions, as in research studies, may help to detect milder but still potentially harmful forms of violence.

The Scale of Sexual and Physical Violence

Official Statistics and Victimization Studies

According to the official crime statistics of the FBI in the United States, in 2017, there were 5.3 murders per 100,000 inhabitants. The estimated rate of aggravated assaults in the same year was 249 per 100,000 inhabitants. Around 135,755 rapes, defined as attempted or completed vaginal or anal penetration with any body part or object, or oral penetration by a sex organ without consent, were reported to law enforcement (FBI 2017, see respective sections for murder, aggravated assaults, and rape). Looking at the representative victimization studies, in the NCVS study, the rate for simple and aggravated assault in 2017 was 13.6 per 1,000 persons age 12 or older (Morgan and Truman 2018). In the same study, rape (defined as coerced or forced, attempted or

completed vaginal, anal, or oral penetration) and sexual assault (defined as attacks or attempted attacks of unwanted sexual contacts other than rape) were reported in 393,980 cases (1.4 per 1,000), of which only about 40% were reported to the police. According to one of the few annual representative victimization studies in Europe, the CSEW, there were 533,248 incidents of violence with injury and 638,894 without injury between October 2017 and September 2018 (CSEW 2018a). In terms of sexual offences, 0.5% of persons aged between 16 and 59 reported being a victim of completed sexual assault by rape or penetration (CSEW 2018b, see Table S36).

Research Studies

Another data source, for both sexual and physical violence, is research studies, such as the recent EU-wide study on violence against women conducted by the European Union Agency for Fundamental Rights (FRA 2014). The FRA study asked women about different acts constituting physical violence (e.g., being pushed or shoved, spalled, grabbed, pulled on hair by someone) from the victim perspective since the age of 15 and in the past 12 months. With respect to sexual violence, the time reference was the same and the scope of considered behaviors ranged from forced oral, vaginal, and anal attempted or completed penetration to any other form of unwanted sexual activity, including being unable or afraid to refuse. Based on interviews with 42,000 women from the 28 EU member states, 33% of them reported physical and/or sexual violence ever, whereby 22% experienced it by a current and/or previous partner. The highest rates were found in Sweden and Denmark (30–39%), the lowest in Poland and Portugal (10–19%). In terms of the last 12 months, 8% of the sample reported physical and/or sexual violence. Extrapolating the figures from the FRA study to the entire EU female population, about 13 million women have experienced physical violence and 3.7 million have experienced sexual violence in the past year.

Important data for both females and males comes also from research studies using the CTS2 (see description in the section [“Measuring Sexual and Physical Violence”](#)). As stated in the recent

article from Straus and Douglas (2017), the CTS2 provides valuable data on the dyadic concordance of experienced acts of violence within a couple. According to the authors, there is a high percentage of violent acts that are experienced by both female and male partners (from their heterosexual partners). As found by other researchers, rates of physical violence toward the partner based on the CTS2 measure were higher in females than in males, i.e., women reported more perpetration toward men and men reported more victimization by women (see Krahé 2013). As Krahé (2013) pointed out, the unexpected difference compared with the well-known gender imbalance in the official crime statistics may be due to different recordings. Official statistics record more severe acts of physical violence compared to research studies based on the CTS2 and generally, more women than men report such acts to the police.

Co-occurrence of Physical and Sexual Violence

While many sources provide data on both physical and sexual violence separately, only some research studies considered both. Based on studies that focused on women who sought help for severe physical partner violence (i.e., battered women), it was found that approximately 30–70% of those women also experienced sexual violence. For example, McFarlane et al. (2005) have shown that 68% of battered women also experienced sexual assault by their partner at least once. Compared to women who were physically abused only, women who experienced both forms of violence started to consume or increased their consumption of alcohol, nicotine, or illicit drugs after the sexual assault. Additionally, those women were 5.3 times more likely to threaten to commit or attempt to commit suicide. Furthermore, a review on marital rape from Bennice and Resick (2003) indicates that victims of marital rape often experienced others forms of trauma, such as physical partner violence, adult stranger rape as well as child sexual abuse, and therefore are at greater risk for posttraumatic stress disorder (PTSD). Similarly, the limited research on male

victims who sought help due to severe physical partner violence (e.g., punching, beating up) has shown that almost 50% of the men reported the experience of minor sexual aggression and 28% reported severe sexual aggression (see paragraph on minor and severe forms of sexual aggression of the CTS2). Among these males, all victimization reports were higher than their perpetration reports. Furthermore, almost all males, who reported severe sexual victimization from their partner, also reported severe physical aggression victimization. As in the battered women samples, male victims of physical violence who also experienced sexual victimization reported more PTSD and depressive symptoms and generally suffered from poor health (Hines and Douglas 2016).

Conclusion

Sexual and physical violence are serious forms of interpersonal violence and social psychology considers them within a broader term of aggression. Data from many sources indicates that a significant percentage of women and men suffer from sexual and physical harm, mostly from people they know. Experiencing both forms of violence increases the risk of suffering more and longer from the consequences of violence.

Sexual Coercion as a Mechanism of Sexual Selection

Melissa Emery Thompson

Department of Anthropology, University of New Mexico, Albuquerque, NM, USA

Synonyms

Sexual aggression; Sexual violence

Definition

Use by a male of force, or threat of force, that functions to increase the chances that a female will mate with him at a time when she is likely to be fertile and to decrease the chances that she will mate with other males, at some cost to the female (Smuts and Smuts 1993, pp. 2–3).

Introduction

Sexual selection theory traces its origin to *The Descent of Man, and Selection in Relation to Sex*, in which Charles Darwin theorized about the evolution of traits involved in reproduction (Darwin 1871). Darwin described two processes: the competition among one sex for sexual access to the other and the expression of choice by one sex for traits expressed in the other. Barbara and Robert Smuts proposed that intersexual coercion be considered as a third mechanism of sexual selection, arguing that there is abundant evidence that males use aggression against females to influence their reproductive success (Smuts and Smuts 1993). Sexual coercion is rooted in interlocus sexual conflict (Watson-Capps 2009), the antagonism that occurs when the optimal reproductive strategy of one sex imposes a fitness cost on the other (Chapman et al. 2003).

Forms of Coercion

Sexual coercion can be divided into two component categories of behaviors (Muller et al. 2009). The first and more widely recognized is *direct coercion*, comprising behaviors that increase the mating access of the coercive male. Direct coercion functions to overcome resistance of a female, either because the male is not preferred or because mating is not desirable at that time. Three major types of direct coercion have been described (Clutton-Brock and Parker 1995). *Forced copulation*, sometimes referred to as rape, involves the use of aggression, restraint, or threat to directly facilitate copulation. *Intimidation* entails retaliation against female mating resistance, decreasing the likelihood of resistance to future attempts. Sexual *harassment* involves repeated attempts to mate which can counteract female resistance when the costs of rebuffing the male become too great. Forced copulations are relatively rare in animal societies but are reported at high rates in humans, orangutans, and some species of waterfowl, cetaceans, and insects. Intimidation and harassment are likely to be commonplace whenever females encounter multiple males, though these tactics have rarely been systematically studied.

Indirect coercion, or coercive mate guarding, includes behaviors used to decrease the likelihood that a female will mate with other males (Muller et al. 2009). *Herd*ing is the use of force to maintain a close proximity between the male and female. *Sequestration* involves physical isolation of females from exposure to other males. *Punishment* entails the use of aggression against females who attempt to associate with or mate with other males. Males using indirect coercion may not encounter resistance to their own mating attempts, and may even be highly desirable mates, but instead use coercive tactics to constrain female promiscuous behavior. There is high potential for indirect coercion in multi-male mating systems, such as those of chimpanzees and baboons, where male competition for fertilization opportunities is intense. However, indirect coercion also arises in pair-bonded species due to the high costs of cuckoldry. In humans, for example, the

prevalence and diversity of female claustration practices across cultures have been attributed to selection for men to protect their significant paternal investment in offspring (Wilson and Daly 1995).

Sexual selection has also shaped the occurrence of infanticide by males of many species (van Schaik and Janson 2000), and this behavior is also broadly consistent with the definition of sexual coercion. Infanticide increases the opportunity for a male to mate with a female, at a clear cost to her fitness, by eliminating the offspring of a rival and decreasing the latency to the next fertile cycle.

Sexual coercion is not synonymous with male aggression against females. Aggression need not be sexual in nature, as males and females encounter other kinds of conflicts (e.g., feeding competition). Conversely, sexual coercion need not include direct aggression, as it may be accomplished by threat of aggression or, in the case of humans, through verbal manipulation or by invoking collateral costs. It can be predicted that males will be most likely to be coercive to females that have a high probability of conception. However, aggressive interactions outside of fertile periods can alter female mating behavior in the future. For species with long-lasting male-female social relationships, males may use aggression as a form of conditioning to alter the future mating behavior of females.

Female Counterstrategies to Coercion

Given the costs of coercion, females should experience selection for counterstrategies (Smuts and Smuts 1993). Females of most mammal species are smaller than males, often significantly so, making it difficult to resist or fight back against a coercive male. Females of some species form coalitions among themselves (e.g., bonobos) or with male “friends” (e.g., savannah baboons) to protect against coercive males. Many female primates exhibit extended receptivity, a feature that can reduce coercion by allowing them to mate with non-preferred males at times when conception is unlikely. Among human societies, sexual

aggression is reduced in human societies where women have access to support from other women and from kin (Smuts 1992). Additionally, while itself the subject of coercive control, women's economic and political power appears to be an important limiter for coercion.

Conclusion

Viewing sexual coercion within the lens of sexual selection theory provides the opportunity to generate and test hypotheses about the evolutionary origins and socioeconomic predictors of intersexual violence, a common occurrence in many animal and human societies. Coercion has been a prominent source of recent research in human evolution psychology, particularly since the publication of the *Natural History of Rape* (Thornhill and Palmer 2000). While that text proposed that human rape may have evolved to overcome female resistance to non-preferred partners, others have argued that many incidences of rape and other forms of sexual violence are attempts to control partner infidelity (Camilleri and Quinsey 2012).

Sexual Conflict After Conception

T. Joel Wade¹, Kelsey Salerno¹ and James B. Moran^{1,2}

¹Department of Psychology, Bucknell University, Lewisburg, PA, USA

²Tulane University, New Orleans, LA, USA

The Adaptive Function of Marital Dissatisfaction During Child-Rearing

It can be argued that the dissatisfaction that occurs in a marriage serves an adaptive function (Shackelford and Buss 1997). Pair-bonding among humans, in particular a union of marriage, likely evolved to increase the reproductive benefits for both sexes (Betzig 1989; Buss and Schmitt 1993). If a marriage is not maximizing the potential benefits and the costs that incur from the relationship outweigh the benefits, then the dissatisfaction that arises would serve to bring awareness of the issues that occur in the marriage. If a couple decides that a relationship is no longer beneficial, then the negative emotions associated with this dissatisfaction would cause one or both of the individuals involved to either address the problems or to end the current relationship to find a more beneficial partnership.

The adaptive challenges for both sexes during a union following conception would have been mate retention and the care of offspring. Since men and women have different reproductive strategies (Buss 1989a), those differences in selective pressure would also lead to men and women facing different adaptive problems during a marriage. A major sex-specific conflict that can arise centers around the issue of paternity certainty. Evolutionary psychologists point out that worldwide cuckoldry rates range from 1.7% to 29.8% (Anderson 2006; Shackelford and Goetz 2007). Additional related conflicts such as violence, decrease in intercourse frequency, kin resemblance, the 4-year itch, and infidelity may also arise after conception.

Research by Lucas et al. (2008) suggests some cultural and evolutionary components to marital satisfaction in general. This research reveals that there may be some universal component to effective communication skills when it comes to raising an offspring, which would have been adaptive in order to successfully raise a child. This theory is further extended by Cox et al. (1999), who found that those couples who had at least one partner with positive problem-solving skills prenatally had higher marital satisfaction than those couples in which neither partner showed this set of skills. Those couples with better problem-solving skills also reported less of a drop in how satisfied they were after the child was born.

Violence During Pregnancy

Violence during pregnancy has been seen throughout history, often being viewed as a product of a patriarchal society. However, evolutionary psychologists view violence during pregnancy as a product of male sexual jealousy stemming from anxiety that the child their partner is carrying is not theirs (Deacy and McHardy 2013). Since men do not have paternity certainty, they may resort to violence against their partner. For women, there is certainty of paternity because fertilization is internal, and women carry the child. Men, however, can be cuckolded and wind up contributing resources to a child who is his genetic offspring.

Cuckoldry ultimately decreases a man's fitness and increases another man's fitness. This potential of being cuckolded is why men are often more upset if their partner commits sexual infidelity rather than emotional infidelity (Kuhle 2011). Upon discovering that a man's partner has become pregnant by someone else, the said man may direct violence against his partner to kill the developing offspring (Friedman and Shackelford 1999 as cited in Buss and Duntley 2011).

Given this risk intimate partner violence is twice as likely in response (Burch and Gallup 2004), and the prevalence of intimate partner

violence during pregnancy ranges from 1% to 20% (Gazmararian et al. 1996). Cross-culturally, this statistics holds true also. A South African study indicates that at least 20% of women experience at least one act of physical violence during their pregnancy (Groves et al. 2015). Additionally, women who are abused are more likely to be pregnant with another man's child (Martin et al. 2004). Similarly, longitudinal research indicates that partner jealousy and partner suspicion of infidelity are strongly correlated with intimate partner violence (IPV) (Hellmuth et al. 2013). These findings clearly show that abuse during pregnancy can be attributed in part to a man's suspicion of infidelity on the part of his partner.

From this previous research, one may reason that IPV could be seen as a form of infanticide also. While abuse may seem to be directed toward the woman herself, a Nicaraguan study indicates half of the women who were pregnant and subjected to violence were injured from attacks directed to their abdomen (Valladares et al. 2005). The abdomen may be targeted in an attempt to kill the offspring, thus terminating the pregnancy.

Prior research indicates that when a man has sex with a spouse, he establishes sexual precedence over her giving him access to her future sexuality (Shotland and Goodstein 1992). This also happens when a man impregnates a spouse (Sales and Murphy 2000). This sexual precedence can be interpreted from an evolutionary perspective where it occurs to try to ensure paternity certainty and monopolize a spouse's reproductive potential.

Male feelings of sexual precedence can also lead to abuse in the form of threats (McFarlane et al. 2002). Communicating threats to a pregnant spouse may serve as a method of mate retention designed to lower her mate value in her eyes which makes it harder for her to feel she can attract another quality mate, keeping her with the father of her offspring. McKibbin et al. (2007) indicate that men can insult their intimate partners as a form of mate retention. But, this has not been tested with men and their pregnant spouses/partners.

After Delivery: Resemblance to Kin as a Decision-Maker to Investment

Due to paternity uncertainty, men may never know if the child they are providing resources for is his genetically related offspring. But, one way a man may seek to resolve this issue is via facial resemblance between him and his offspring. Research indicates that when families observe newborn babies, both the mother and her family claim the newborn looks like the father (Daly and Wilson 1982). This represents an underlying mechanism attuned to familial resemblance of the father in order to facilitate parental investment by the father. Research supports this. Burch and Gallup (2000) report that violence directed to the child and the mother is negatively correlated with a greater sense of paternal resemblance. Also, men react in a more positive manner and invest more, hypothetically, when an offspring resembles them (Platek et al. 2002, 2003). As paternal resemblance and mate fidelity increase, so does the increase in investment to the offspring (Apicella and Marlowe 2004). Furthermore, the area of men's brains that play a role in decision-making respond differently to resemblance, compared to women's brains (Platek et al. 2004). These findings suggest that facial resemblance is an important factor for paternal investment in offspring and as such suggest that kin resemblance may play a role in conflict after conception occurs.

Problems After the First Child

Four-Year Itch

Couples often have a decline in marital happiness after approximately 4 years (Fisher 1989; Kurdek 1999), and researchers have speculated that it could be the outcome of boredom in a marriage (Kurdek 1999). From an evolutionary perspective, there may be a biological drive for a new partner after 4 years because 4 years are the typical amount of time needed to ensure the survival of the hominid infant through weaning (Fisher 1989). Infants are altricial when they are born and require an extensive amount of care.

Therefore, infants are mother nurses, and nursing stimulates a release of oxytocin which facilitates attachment between mother and infant (Feldman et al. 2007; Galbally et al. 2011).

Transition to Parenthood (TTP)

Prior to having their first child, the couple begins to make plans and anticipate the future with one another, and after the birth of the first child, they experience joy but also experience negative effects like an extreme focus on their health and the offspring's health. Additionally, they experience a decline in income and an increase in labor (Myrskylä and Margolis 2014). Given this conflict, not surprisingly, when a child is born, it has negative impacts on the couple's marital relationship (Belsky et al. 1983). In fact, Kurdek (1999) reports that couples with children experience the steepest decline in marital quality. Similarly, Twenge et al. (2003) in a meta-analysis from 148 samples report that across 90 studies parents had less marital satisfaction than non-parents, with a 10% difference among these groups in the reports of above average marital satisfaction. Research shows that married couples experience a decrease in satisfaction and confidence in their relationship and an increase in negative communication and poor conflict management (Doss et al. 2009).

From an evolutionary perspective, the decline in satisfaction due to conflict can be accounted for by selective pressures. For example, men take the role of fatherhood more negatively than women (Gray and Crittenden 2014), since men typically are more interested in short-term mating (Buss and Schmitt 1993), consistent with parental investment theory. A woman may not be as stressed with the arrival of a child because she is more interested in long-term mating (Buss and Schmitt 1993) and because she is certain that the offspring is hers, whereas men may not have paternity certainty (Trivers 1972).

In our current world, children are also weaned earlier than they were in ancestral societies which lead to more involvement in child-rearing from the father. This adds an additional stressor of an increased need for cooperation between parents to raise their young. This stressor likely contributes

to fathers experiencing less marital satisfaction (Doss and Rhoades 2017).

Other moderating factors that may also contribute to increased conflict and decreased marital satisfaction are the gender of the parent, the age of offspring, and the number of offspring (Twenge et al. 2003). Correlational data indicate that women typically have less marital satisfaction than men. Furthermore, women who had infants also reported less satisfaction than women who did not have infants, while those women with infants had only a slight difference in reports of satisfaction compared to those women with older children. The age of children did not affect men's marital satisfaction. Furthermore, those parents who had a greater number of children also revealed less marital satisfaction (Twenge et al. 2003). Overall, this research suggests that parents with multiple children and women with children have less marital satisfaction than parents with one child and childless women.

As Trivers (1972) details, there is a sex difference when it comes to parental investment. Fertilization and gestation occur internally for females, with male's minimal contribution to having offspring being ejaculation. After birth, women are the providers of nutrients to the child through breastfeeding, which in previous times occurred for the first 3–4 years of a child's life. From a parental investment theory perspective, it is not surprising that women with younger children have less marital satisfaction since they have to devote greater time and effort to care for a younger child. The mothers also tend to do significantly more housework, 9 h more than their childless counterparts, while fathers only completed an hour more than those childless men (Nomaguchi and Milkie 2003). This dissatisfaction can be offset by a husband who invests more in the child by dedicating more time to the rearing of the child (Gjerdingen and Chaloner 1994). A greater investment by a male into his offspring is something women typically look for when choosing a mate (Buss 1989a). Therefore the greater investment by a man would fulfill this preference and cause less strategic interference among the couple (Buss 1989b, 2001). Overall, there would be less conflict because the burden of child-rearing and care would be lessened.

Socioeconomic status (SES) is another moderator variable that affects marital conflict and satisfaction. Twenge et al. (2003) report that parents of higher SES, as well as the cohort of parents from the newer generation, reported greater marital dissatisfaction. The authors suggest that these findings may be explained using two models: role conflict model and restriction of freedom models. It may be that greater emphasis that is put on autonomy (Frum 2000), as well as an increase in the choice of activities that can be restricted when one becomes a parent, that contribute to greater dissatisfaction in marriage. The role that each sex typically takes on when it comes to parental investment applies also. With a greater shift in women entering the workforce now, married/partnered women of higher SES may be experiencing greater dissatisfaction than those married/partnered women of lower SES or married women of previous generations because the transition to parenthood may be more pronounced. Also, with more women working now, additional conflicts may arise because women have less time to devote to child-rearing and may need additional support from the child's father.

Sex After the First Child

A common feature throughout the human population is a decline in sexual intercourse (Brewis and Meyer 2005). Before the birth of the child, women's sexual interest and activity declines during the first trimester and continues to decrease into the third trimester (von Sydow 1999). Additionally, after the child is born, sexual interest is usually lower than normal for several months. Furthermore, research on women's sexual interest indicates that they have less of a desire to have sex after having children (Brewis and Meyer 2005; Abdool et al. 2009; Escasa-Dorne et al. 2013). Men's sexuality also shifts during the TTP. Although they do have a satisfying sex life, men's sex drive is more inconsistent after the first child is born (Gray et al. 2015). This decreased libido on the part of men can be due to a decrease in testosterone since men's testosterone goes down after they have a child (Gray et al. 2002). Since men and women, respectively, are

less interested in sex after a child is born and sexuality in personal relationships is the result of an underlying motivation to maximize the transmission of genes to succeeding generations (Sprecher and Cate 2004), conflicts can arise regarding the amount of sex desired. Long et al. (1996) report that sexual conflict is negatively related to relationship satisfaction.

Infidelity and Jealousy

Two common types of infidelity that occur in relationships are sexual and emotional infidelity. Sexual infidelity involves having sex with someone other than your primary partner, while emotional infidelity involves falling in love or diverting resources such as time investment, attention, and emotional support to someone other than the primary partner (Shackelford et al. 2004; Shackelford and Buss 1997). While both types of infidelity can be distressing, a sex difference emerges for reactions to infidelity dependent upon the type of infidelity committed. For men, if a woman is adulterous, it threatens his paternity certainty and opens the possibility of him being cuckolded into raising offspring that would not contribute to furthering his genetic line. This potential risk causes men to be more upset by sexual infidelity compared to emotional infidelity (Buss et al. 1992).

For women, a male partner who commits emotional infidelity signals a loss of investment in the couple's offspring since some of the man's time and resources are diverted to another woman and possibly to this other woman's offspring. Thus, women are more upset by a partner's commission of emotional infidelity. So, the jealousy each sex experiences most is dependent on the type of infidelity their partner commits (Wiederman and Kendall 1999). This differential jealousy adaptation helps to ensure one's own fitness (Bendixen et al. 2015).

Researchers have discovered that during pregnancy, men are more likely to commit infidelity (Whisman et al. 2007). This may occur because there are reproductive advantages gained by having extra-pair copulations. If a man has multiple

partners that he reproduces with, then his fitness is increased, and his genetic legacy is likely to continue. But, getting caught cheating on a partner can cause a high level of conflict, leading to mate expulsion, depending on the type of infidelity committed (Shackelford et al. 2002).

Since men are likely to commit infidelity when a woman is pregnant, conflict may arise in the couple such that women engage in more mate guarding. This would be adaptive since sexual infidelity on the part of her male partner could lead to a loss of investment in her offspring. Not surprisingly, Graham-Kevan and Archer (2009) report that pregnant women do engage in more mate guarding than nonpregnant women.

Conception may lead to conflict based in error management theory (EMT) because Buss (2001) reports that inferential biases are made about potential infidelity. From an EMT perspective, there are costs and benefits associated with overestimating the potential for sexual infidelity. So, in certain contexts, as in the case of a pregnant partner, it would be especially advantageous for a man to use heightened mate retention and mate-guarding tactics due to an overestimation that the partner would commit sexual infidelity. A man with a pregnant partner could experience reproductive losses if he underestimates his pregnant partner's potential for sexual infidelity. Each of these situations could cause conflict among the couple because the mate-guarding tactics utilized by the man could become too controlling, or they could become not controlling enough to guard against a loss.

Child Custody and Child Support Conflict

Shackelford and Buss (1997) explain that marital satisfaction is an adaptive function because it allows the couple to realize it is time for them to find a different partner. If the couple decides to dissolve their relationship, and they have children, conflict can arise.

Since, the individuals are no longer living together, one of the individuals must help provide for the child. Consistent with parental investment

theory (Trivers 1972), usually women are the ones in heterosexual relationships to gain custody of the child (Anderson 2011; Grall 2007). Men's largest investment is financial which can lead to conflict after relationship dissolution.

In 2011 the US Census Bureau estimated that \$37.9 billion dollars in child support was owed during the year of 2011, and 53.4% were single mothers (U.S. Census Bureau 2013). This statistics suggests that men are being forced to pay their ex-wives money to help provide for their child. Research speculates that although it may be advantageous for men to invest in their child, even if they are not living with them, it may also benefit them in not supporting the child (Shackelford et al. 2005). Men may refuse or want to reduce their payments of child support, because if they are giving money to an ex-partner they do not have 100% certainty that the money is going to their offspring and not to their ex-partner or their ex-partner's new partner. If this occurs, then the man is ultimately decreasing his fitness by giving up resources to an individual that is not his mate. A man may also want to reduce or not pay his child support if he has a new partner, since women tend to prefer men who are good financial providers (Buss 1989). Men may want to divert funds away from their child support and use those funds to attract a new mate, which will ultimately increase his fitness. This can create conflict among the man and the mother of his child requesting the child support. The aforementioned research shows that evolutionary theory can explain sexual conflict after conception occurs.

Sexual Conflict and Sex Differences in Parental Investment

Stephanie R. Fahey and Joseph A. Camilleri
Westfield State University,
Westfield, MA, USA

Sexual conflict occurs when the evolutionary interests of males and female diverge, leading to antagonistic coevolution (Härdling and Smith 2005; see Parker 1979, 2006; Trivers 1972). There are two types of sexual conflict: *Intralocus sexual conflict* occurs when a trait is expressed in males and females but has opposing fitness outcomes, whereas *interlocus sexual conflict* is when a trait in one sex conflicts with a different trait in the other sex.

There is sexual conflict over parental care because one sex would benefit if the other sex invested more in their offspring. More specifically, mating strategies differ between the sexes due to differences in minimal obligatory parental investment (i.e., minimal investment required to produce offspring). Parental investment theory (Trivers 1972) suggests that the sex with greater obligatory parental investment, typically females, can increase fitness by being more discriminative in mating partners (e.g., screen for those with better genes, resources, or willingness to invest in offspring), whereas the sex with lesser obligatory parental investment, typically males, can increase fitness through increasing the number of mateships with the more investing sex. In humans, women's minimal obligatory investment is greater than men's because it includes 9 months of gestation and early child care until weaning, whereas men's minimal obligatory investment amounts to a single mating. Thus, there is conflict over mating effort and parental investment when each sex pursues their optimal strategy (Bjorklund and Shackelford 1999; Goetz and Shackelford 2009).

In humans, parental investment can be understood as a form of interlocus conflict if men's high

mating effort with low parental investment conflicts with women's preference for a committed and investing mate. Parental investment can also be understood as a form of intralocus conflict if there are opposing fitness outcomes to parental investment. These examples meet the criteria for sexual conflict if the beneficial trait in one sex is associated with a cost to the other sex. To date, no direct empirical tests of sexual conflict in parental investment have been conducted with humans, though some research is consistent with these ideas. Women generally invest more time in child care than do men; women are also more likely to gain child custody; and there is conflict over men failing to provide child support (see ► [“Child Custody”](#) and ► [“Child Support”](#) entries).

Sexual conflict over parental investment has been more directly applied and empirically tested with nonhuman species (Westneat and Craig Sargent 1996), particularly birds (Royle et al. 2002; Slagsvold and Lifjeld 1989), with at least one study using meta-analytic methods (Harrison et al. 2009). Mathematical models also show promise in understanding sexual conflict and sex differences in parental investment (Lessells and McNamara 2012). Applying such methods to humans would address some of the difficulty in studying fitness outcomes from parental investment.

Definition

Sexual conflict in mating strategies occur when men and women come into conflict as a result of pursuing different mating strategies with non-overlapping or opposing objectives.

Introduction

Why do men and women come into conflict over mating and sex? This chapter examines the adaptive reasons, which trace back to key differences in minimum obligatory parental investment (Trivers 1972). Reflecting these differences, men tend to be relatively eager for casual sex, whereas women are relatively more cautious, requiring their sexual partners to be of higher quality or committed for a longer duration. As each side strives for its own reproductive interests, the other side's strategy is often interfered with, resulting in conflict.

Evolutionary Roots of Sexual Conflict in Mating Strategies

In most sexually reproducing species, females are physiologically obligated to make a larger minimum investment than males of time, energy, and resources to produce and develop offspring. In mammalian species, offspring develop inside the female and rely on the mother for nourishment and nurturance for the first few years of life. Although males often make significant parental investments, their *minimum obligatory* investment consists mainly of their sperm. Due to the large discrepancy in minimum required investment, females are more reproductively valuable and have evolved to be choosier about potential mates because mating mistakes are costlier to them. That is, females increase their overall reproductive success by ensuring that their sexual partners have sufficient genetic and material resources that they are willing to share (Buss and Schmitt 1993; Symons 1979). Human males, on the other hand, are much less biologically constrained and have evolved to compete for sexual access to

females (Bjorklund and Shackelford 1999; Trivers 1972). Indeed, males are able to increase their overall reproductive success by increasing the number of partners that they inseminate – a generally undesirable strategy for human females, who are potentially bound to several years of maternal investment for any given sexual encounter. Therefore, whereas human males tend to benefit relatively more than females from pursuing a mating strategy of quickly amassing reproductive *quantity*, human females tend to benefit more relative to males from pursuing a strategy of slowly and carefully ensuring *quality*.

This asymmetry in reproductive costs and benefits shapes the variation in strategies preferred by men and women in their pursuit of sexual relationships with each other. As shown below, the resulting divergence in mating strategies is a source for much potential sexual conflict (Goetz and Shackelford 2009).

Sex Differences in Standards and Eagerness for Casual Sex

Stemming from differences in minimum required parental investment and the associated asymmetry in costs and benefits, men have evolved lower standards and greater eagerness for casual sex, whereas women have evolved to have higher standards and greater caution toward casual sex (Symons 1979). Men's lower standards have been demonstrated across numerous surveys (e.g., Buss and Schmitt 1993; Li et al. 2002). For instance, one study asked people to indicate the minimum acceptable percentile level for 24 different characteristics pertaining to a potential partner for a single date, sexual relations, steady dating, and marriage (Kenrick et al. 1990). Whereas women's minimum requirements started out relatively low for a date and rose steadily as the relationship became more sexual and significant, men's minimum requirements were significantly lower than women's for both dates and for sexual relations.

Take intelligence for instance. Both sexes required potential dates to be at the median level of intelligence, and both sexes required their

steady dating and marriage partners to be clearly above the median. However, whereas women required their sexual partners to be above the median on intelligence, men were willing to accept a one-night stand whose intelligence was low (31st percentile; Kenrick et al. 1990). Other surveys have similarly indicated that compared to women, men desire and anticipate having more sexual partners (e.g., Simpson and Gangestad 1991), desire greater sexual variety, and have more sexual fantasies.

Behaviorally, men are the primary consumers of pornography and prostitution, and are also more likely to engage in extramarital affairs. In a set of classic field studies (Clark and Hatfield 1989), opposite-sex students were randomly approached on campus by experimenters and told, "I have been noticing you around campus. I find you to be very attractive." They were then either asked to "go out with me," "come over to my apartment," or "go to bed with me" that evening. For a simple date, men and women were similarly likely to accept the invitation – roughly half of each sex said yes. However, as the likelihood of immediate sexual intimacy increased, the sexes sharply diverged in their responses. While a meager 3% of the women agreed to go back to the man's apartment, nearly 70% of men consented to heading to the woman's apartment. For the more direct sexual request, not one woman agreed, and many were clearly upset at having been sexually solicited (e.g., "What is wrong with you? Leave me alone."). In stark contrast, more than 70% of men agreed to the sexual invitation, with some expressing greater urgency (e.g., "Why do we have to wait until tonight?"). Men who declined made sure to indicate mitigating circumstances ("I'm going with someone") or affirm their underlying interest (e.g., "I can't tonight but tomorrow would be fine.").

Conflict Concerning if and when Sex Occurs

Given that men and women diverge significantly in their focus on short-term quantity versus long-term quality and their attitudes toward casual

sexual relations, it is not hard to imagine men's and women's mating strategies coming into conflict. Whereas women are more interested in having sexual relations with partners of sufficient quality who can invest, men prefer having many low-cost sexual relationships and to have them sooner versus later. The subsections below describe how these strategies come into conflict in the way that men and women infer sexual intent and how men, being more eager, may push for their interests while women, being more cautious, resist.

Error Management Theory

People often make judgments under conditions of uncertainty, whereby they do not know the exact states of factors relevant to their decisions. According to error management theory (Haselton and Buss 2000), such decisions effectively pit a Type I error (falsely inferring the existence of a particular state) against a Type II error (falsely denying the existence of that state). For recurrent situations of reproductive significance, humans likely evolved a systematic bias to make related decisions that favor committing the less costly error.

One such situation involves inferring sexual intent in opposite-sex others. For men, additional sexual partners can contribute directly to reproductive success. However, because women tend to be cautious about casual sex, most men do not have access to many casual sexual partners (Symons 1979). Thus, a Type II error – incorrectly inferring a lack of sexual interest when it is actually present – means losing valuable reproductive resources. In comparison, a Type I error – incorrectly inferring sexual interest when it is absent – results in a comparatively smaller cost of wasted time and effort (Haselton and Buss 2000). Given this cost asymmetry, men may have evolved to overinfer sexual interest in women.

For women, casual sex does not offer the same gains in reproductive success, and potential casual sexual partners are not scarce. Thus, missing a sexual opportunity from falsely inferring a lack of sexual interest is not particularly costly for women. However, women would incur a potentially expensive error if they were to have sexual

relations after falsely inferring commitment from their potential mates (Haselton and Buss 2000). Such a mistake could lead to tying up years of reproductive resources without the support of paternal resources. In comparison, incorrectly inferring that male commitment is insufficient is not as costly, as such an interpretation may also encourage additional or greater displays of quality, investment, and commitment from potential partners. Thus, due to asymmetries in the costliness of errors associated with assessing male relationship commitment, women have likely evolved a commitment skepticism bias (Haselton and Buss 2000).

Directly investigating sexual intent, a classic study randomly placed people into male–female pairs and assigned them to be actors chatting for 5 minutes, or observers instructed to watch the conversation through a one-way mirror (Abbey 1982). Both male observers and actors perceived females having conversations to be more promiscuous and more platonically, romantically, and sexually interested than female observers and actors did. Male actors and observers also reported greater sexual attraction toward the female actor than female actors and observers reported toward the male actor.

Although various explanations have been proposed for these findings, Haselton and Buss (2000) empirically demonstrated that sex differences in the perception of sexual intent reflect error management theory. Specifically, they showed that people are not simply projecting their own views onto their perceptions of sexual intent in opposite-sex others, and that men's perceptions of women's sexual intent differ for a potential mate versus their sister. The latter finding indicates that men are not simply ascribing greater sexual intent to all women but, rather, just to those who constitute potential mates.

Sexual Aggressiveness

Behavioral conflicts may also be induced by sex differences in perceptions of sexual intent as well as the underlying sex differences in desired sexual urgency. This section covers two broad categories of sexually aggressive behavior: sexual

harassment and rape. Whereas sexual harassment involves unwanted or unsolicited sexual attention in general, rape more specifically focuses on the use of coercive physical force to achieve sexual intercourse.

Sexual harassment: Mating conflict in the workplace. In the modern workplace, men and women spend a significant amount of time coming into close contact and getting acquainted with each other. Such an evolutionarily novel environment may be especially conducive to the development of conflicts in mating strategies, as opposite-sex co-workers who can potentially be attracted to each other are expected to interact nonsexually. Indeed, in some work environments, up to 90% of women have reported being sexually harassed in some form.

In the United States, sexual harassment laws grant legal recourse to individuals who receive “unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature.” Such conducts cover an extensive range of behaviors, including staring in a sexually suggestive manner; making remarks considered offensive about looks, clothing, or body parts; touching (e.g., patting, pinching, or intentional brushing against another’s body); telling sexual jokes or displaying sexually suggestive posters; making sexual gestures; and sending, forwarding, or soliciting sexually suggestive letters, notes, e-mails, or images. Since the mid-1990s, over 10,000 sexual harassment charges have been filed each year. Consistent with sex differences in reproductive strategies, the large majority of filers are female.

A well-publicized sexual harassment case occurred when Paula Jones filed charges against President Bill Clinton in 1994. According to Jones’ testimony, while Clinton was governor of Arkansas, he exposed his penis to Jones, who was then an employee of the state of Arkansas, and asked her for oral sex in a hotel room. Over the next few years, the president’s sexual history was investigated and made public, but the eventual ruling was that there was insufficient evidence that Jones had suffered any emotional damage. Nevertheless, Clinton settled out of court for \$850,000 (with no apologies).

Another interesting case involves the supermarket chain Safeway, which, in the late 1990s, reinstated a “superior customer service” policy requiring employees to smile, make eye contact with, and warmly greet customers by their name. In the duration of the Safeway program, various female employees were asked about their marital status, propositioned for dates, touched, grabbed, and followed after work to their cars by male customers. Five female employees filed formal charges with the Equal Employment Opportunity Commission, alleging that the Safeway program encourages sexual harassment by creating a hostile work environment.

Both the Clinton and Safeway cases reflect mating-related *strategic interference* (Buss 1989) – violations of one’s preferred mating strategy – in the workplace. That is, much of the sexual harassment that occurs ultimately stems from fundamental sex differences in preferred mating strategies, whereby men are more eager for sexual relations and women are more cautious. In this view, laws governing sexual harassment specifically target the violation of a slow mating strategy by discouraging men (and some women) from pursuing or showing signs of a relatively eager sexual strategy and acting upon potential over-perceptions of sexual interest (as well as strategically feigned displays of interest).

Studies focusing on the characteristics of alleged targets of sexual harassment lend further support to a strategic interference perspective. For example, younger women tend to be more frequently harassed than older women, reflecting men’s preference for younger, and implicitly more fertile, mates (Buss and Schmitt 1993). In fact, people are less likely to believe that a woman who claims sexual harassment was actually harassed if she is physically unattractive – and thus, less sexually desirable – than if she is attractive (Seiter and Dunn 2001). Similarly, women are more likely to be upset by persistent unwanted advances from low-status men such as garbage collectors and janitors than by high-status men such as graduate students and rock stars (Buss 2003). Such findings indicate that sexual harassment is not random conflict, but rather, it stems from one sex pursuing their evolved mating

preferences without the full consent of the other sex, who has their own preferences and standards.

Although men are typically blamed for their unwanted sexual advances, some findings suggest that women's behaviors may play a role in triggering men's overperception of sexual interest. For instance, women, significantly more than men, report smiling and flirting to elicit special treatment from the opposite sex, despite having no sexual interest toward such individuals (Buss 2003). In such cases, men's evolved sexual eagerness is being exploited which may, at times, contribute to sexual harassment.

In summary, the modern-day workplace presents an evolutionarily novel context in which men and women work, interact, and come into close contact with each other. As such, it constitutes a potential mating market as well as a stage for sexual conflict. Various studies are consistent with the possibility that sexual harassment typically occurs as a result of sexual conflict over mating strategies. Although co-workers or customers and service staff are not expected to get sexually involved, they might get attracted to desirable members of the opposite sex in these contexts. Regardless of their social or work roles, men who are relatively more eager for sex may be suggestively indicating their interests toward women, who are strategically more hesitant and who may falsely suggest sexual interest in order to coax other forms of investment from the men. Importantly, and consistent with an evolutionary perspective, sexual advances are more likely to be unwanted, and thus, viewed as harassment, if they involve less socially desirable male perpetrators and younger and more physically attractive female targets.

Rape. A more direct and serious conflict involves forced sexual intercourse or rape – an act that is not limited to humans. Take scorpionflies for instance. When male scorpionflies have access to viable food sources (e.g., arthropods), they typically present food gifts to females, who accept such gifts while offering sexual access in return. However, when food gifts are unobtainable, males will sometimes use their anatomical clamps, or “genital claspers,” to hold the wings of female scorpionflies in place in order to force copulation. Males that are

smaller and less capable of securing food are typically the ones who use their clamps to secure matings (Thornhill and Palmer 2000).

An example closer to humans involves orangutans (Wrangham and Peterson 1996), for which there are two male forms: adult and subadult types. Whereas adults are physically larger, more dominant, and more adept at obtaining consensual matings with females, subadults are generally smaller and less dominant and have difficulty finding interested and willing sexual partners. Consistent with this distinction, subadult males have been observed to be more likely to force copulation onto females than adult males. As with the scorpionfly, the forced matings pursued by subadult orangutans are more the exception than the norm and seem to reflect conditional mating strategies. That is, when such males fail in intrasexual competition or are otherwise unable to provide females with the necessary resources to facilitate consensual sexual relations, the males adopt sexual coercion as a last resort to gain sexual access.

Rape in humans is a widely studied topic. As with sexual harassment, the victim is usually female. In one survey, 54% of American women reported some form of sexual victimization, while 27% reported experiencing rape or attempted rape (Koss et al. 1987). Perpetrators might be strangers, but more than 80% of sexual victimization cases deal with acquaintances, boyfriends, or husbands.

Drawing from an evolutionary perspective, some theorists have proposed that male rape might be an adaptive, conditional mating strategy, such as the ones employed by male scorpionflies and orangutans. Specifically, Thornhill and Thornhill (1983) argued that men may have evolved to rape (or be more likely to rape) when they are unable to obtain a mate through intrasexual competition. This view has been termed as the “mate-deprivation hypothesis” (Lalumiere et al. 1996). Shields and Shields (1983) proposed a similar hypothesis with an additional integration of sociocultural theories of male hostility and power. Both sets of researchers argued for greater attention to be paid to an evolutionary perspective and advocated

the use of a reproductive cost–benefit approach to understanding rape.

More recently, Thornhill and Palmer (2000) presented and evaluated two evolutionary conceptions of rape. On the one hand, rape may be a by-product of other evolved mating mechanisms, such as the male desire for low-cost (minimal courtship) mating and sexual variety. On the other hand, rape could represent a specialized adaptation that activates under certain circumstances. As part of the adaptation, men are hypothesized to have various psychological mechanisms that promote this strategy, including the ability to assess the vulnerability of potential rape targets, a rape mindset that activates when sexual access to consenting partners is blocked, preferences for young and fertile females, and sexual arousal in response to female resistance to men's sexual advances (Thornhill and Palmer 2000).

There is a fair amount of evidence for rape as an evolved mating strategy (see Camilleri and Stiver 2014). For instance, an important prediction made by the rape-as-adaptation hypothesis is that male rapists should have a preference, if not requirement, for fertile females. The potential costs of rape in ancestral times were relatively large and included retaliation from the female, her kin, and her long-term romantic partners. Given such costs, an evolved strategy for male rape should be designed by selection to be particularly attuned to targeting females most likely to bear children. Indeed, similar to those claiming sexual harassment, rape victims appear to be disproportionately in their early 20s (Shackelford 2002) when fertility is highest, with almost 80% of rape victims in the age range of 16–34. It might be argued that this finding is a by-product of women in this age group being more likely to associate with young men, who are themselves the age group most likely to engage in criminal activities in general. However, a comparison between the age distributions of rape and murder victims contradicts this explanation (Thornhill and Thornhill 1983) – murder victims tend to be older than rape victims and are not concentrated among individuals in their 20s.

The most direct evidence of rape's potential reproductive gains for men comes from

pregnancy rates of rape victims. Whereas consensual-pregnancy rates are around 3%, rape-pregnancy rates are significantly higher, near 8% (Gottschall and Gottschall 2003). The majority of rape pregnancies were also concentrated in the 15–24 victim age range. However, rapists' targeting of reproductively aged women may be interpretable from other mating mechanisms. When choosing partners, men are found to have a preference for young women, especially those in the most fertile age range (Buss and Schmitt 1993; Symons 1979). Thus, rapists' choice of fertile targets might reflect an expression of typical male mate preferences. Greater pregnancy rates in rape victims might be due to male sensitivity to female ovulatory cues, coupled with the fact that the rapist is, unlike nonrapists, unconstrained by female choice.

On the other hand, the mate deprivation hypothesis has not received much support for its prediction that men who are unable to obtain mates will tend toward rape (e.g., Lalumiere et al. 1996). In fact, men who reported being physically and non-physically sexually coercive also reported having *higher* mating success and *more* sexual experience. Although this appears to contradict the adaptation hypothesis, it is possible that this survey tapped into a more modern form of “date rape” committed by males who are capable of getting dates but use aggression to speed up or increase the likelihood of copulation, rather than deprivation-motivated (or “loser male”) rape, which could involve strangers and is likely rare among college students. Indeed, a more nuanced evolutionary conception of rape has been proposed by others (McKibbin, Shackelford, Goetz, and Starratt 2008; but c.f. Camilleri 2012). Taking a domain-specific approach, they proposed that five distinctly different types of rapists may have evolved for specific functions: disadvantaged men, specialized rapists, opportunistic rapists, high-mating-effort men, and partner rapists. Perhaps it is useful to conceive of mate-deprivation motivated rape not as a single adaptation but as an initial filter through which other rape adaptations have evolved (Camilleri 2012, p. 180).

While further support for general or specific male rape adaptations is still needed, rape

nevertheless constitutes a violation of females' mate choice and preferred mating strategy. Regardless of its ultimate cause, rape, to the extent that it recurrently occurred in the ancestral past, would have exerted selection pressures for female adaptations to prevent rape.

Evidence for Female Antirape Adaptations

One candidate for a female antirape adaptation is psychological pain from rape. Physical pain draws attention to a part of one's physiology that needs tending to, whereas mental pain draws attention to the social circumstances leading to the pain and motivates avoidance of future similar situations. For example, people become upset in response to having been sexually deceived, which prevents similar mistakes in the future (Haselton et al. 2005). A series of studies reported by Thornhill and Palmer (2000) found that rape victims who were reproductively aged experienced more psychological trauma from rape, as compared with pre- and post-reproductively aged women. Furthermore, vaginal intercourse during rape led to greater psychological trauma – but only in reproductively aged victims. This highlights the sensitivity of psychological pain to the magnitude of the reproductive costs involved, whereby reproductively aged women are the most likely to be impregnated by an undesirable mate as a result of rape.

Trauma experienced by rape potentially serves a corrective purpose, driving the victim to be acutely aware of relevant dangers and to avoid them at all costs. But without previous experience, women also seem instinctively avoidant of risky behaviors, especially when the cost of rape is highest. One such situation is when women are in their ovulatory phase – the one-or-two-day window each month when the chance of conception is highest. For instance, one study asked female participants to evaluate a set of activities on how likely these activities would place someone in a position that is “vulnerable to sexual assault” (Chavanne and Gallup 1998, p. 29). A separate group of females indicated which activities, among the set, they had carried out in the past 24 hours. As predicted, using a composite

score across all activities, participants indicated taking the least amount of risks during their ovulatory phase. Criticizing their use of a composite risk-taking score, others performed a follow-up variant of the study and found that ovulating women specifically increased their nonrisky activities, such as reading at home, while avoiding risky activities, such as getting drunk or walking alone in a park. Another intriguing study found that female handgrip strength significantly increased after women read a hypothetical sexual assault scenario and that this effect was specific to women in their ovulatory phase (Petrallia and Gallup 2002). The researchers interpreted the findings as tentative evidence for a female adaptation to resist rape when pregnancy risk is highest.

Female rape avoidance behaviors have also been found to increase with other individual factors, such as greater physical attractiveness, already having a mate, and not being socio-sexually oriented towards short-term, casual sex (McKibbin et al. 2010). In general, women's rape avoidance behaviors may serve the functions of avoiding: strange men, being viewed as sexually receptive or being alone, and having a heightened awareness of one's surroundings in the interest of defensive preparedness.

To the extent that rape is a sexual conflict, its enactment (versus prevention) confers reproductive benefits onto one sex while exacting costs on the other. Rape is not only costly to females by circumventing their mate and reproductive timing choices, but can also cause physical injury and might lead to abandonment by the female's current mate (Thornhill and Thornhill 1983).

Conflicts of Deception

Conflict can also occur when individuals misrepresent themselves or their intentions to further their own mating strategy but are later found out. Although some deception is not specific to a particular sex, an evolutionary perspective would also predict that much deception would be patterned around the different mating strategies and

mate-selection criteria used by men and women (Buss 1989; Haselton et al. 2005). The prevalence of mating-related deception has been documented in many studies. For instance, people lie to others in more than 25% of their daily social interactions. In mating contexts, both sexes use a diverse set of deceptive acts, both intra- and intersexually (Haselton et al. 2005).

One major type of sexual deception involves misrepresenting one's sexual intentions. As described earlier, men around the world consistently desire a greater number of sexual partners than women do (Buss and Schmitt 1993). Given that men are more eager for sexual relations than women are, it comes as no surprise that men, more than women, are deceptive in service of obtaining sex. In one study 71% of college men admitted to having exaggerated their love and commitment to their potential mates in order to have sex (Buss 2003).

Women, more than men, report having used sexual teasing – intentionally offering some form of sexual contact and withdrawing that offer (Meston and O'Sullivan 2007). As described above, many women admit to flirting with men with whom they have no intention of having sex in order to extract favors from these men (Buss 2003). Correspondingly, more men than women report having been sexually “led on” and being emotionally upset in response to being deceived about sexual access (Haselton et al. 2005). Newlywed women are more likely than newlywed men to report having acted coy and having played hard to get as tactics in attracting their spouse. Thus, while sexual teasing might be an effective female strategy to extract favors and resources from men who are trying to employ a short-term mating strategy, it may also have the effect of allowing women to more effectively fulfill a long-term mating strategy.

On the other hand, men, more often than women, misrepresent their commitment and interest in long-term relations in order to obtain sexual access. This strategy is especially favored by men who are narcissistic, Machiavellian, and psychopathic – “Dark Triad” traits associated with being more sociosexually unrestricted, having

more lifetime sexual partners, and more actively seeking out short-term sexual partners (Jonason et al. 2009). Taken together, these patterns suggest that, regarding sexual access, each sex may be misrepresenting compliance with the other sex's preferred mating strategy in order to promote their personal interests and mating goals.

Conclusion

Sexual conflicts in mating often involve differences in how sexual intent and sexual deception are perceived by men and women. These differences originate from asymmetries in parental investment and can result in sexual harassment and rape. Although men often invest heavily in their children, only women are physiologically obligated to make a substantial initial parental investment (Trivers 1972). This key difference selects for different optimal mating strategies for men and women. Whereas men have evolved to seek greater numbers of fertile mates, women have evolved to be more careful about ensuring that potential sexual partners are of high quality and are willing and able to invest in them and their offspring (Buss and Schmitt 1993; Symons 1979). Therefore, as many studies show, the sexes' preferred mating strategies will often come into conflict. Compared with women, men's eagerness for sex tends to induce overperceptions of sexual intent and greater sexual aggressiveness, which may result in sexual harassment and even coerced sex. Furthermore, members of each sex often deceive the opposite sex (potential mating partners) to induce them to comply with their own preferred sexual strategies. This is done by creating the false impression in the opposite sex that they (the opposite sex individuals) are successfully enacting their own preferred sexual strategies.

Although research has covered a lot of conceptual and empirical ground, there are still various important dimensions related to this topic that have yet to be investigated or considered. For instance, female harassers have been found to be disproportionately younger, single, and more

attractive than the average working woman (e.g., Studd and Gattiker 1991). From an evolutionary perspective on mating conflict, such female harassment might be interpreted as attempts by unmated women to solicit potential partners. However, why especially desirable women would need to harass their potential mates is baffling and requires further explanation. Readers are advised to keep posted for future developments on this topic.

Definition

Sexual conflict is the disagreement over investment that ensues because males and females adopt or develop strategies that are only aimed at increasing their own fitness, but that impose a cost on the mating partner.

Introduction

Males and females differ in their reproductive investment, resulting in what is called “sexual conflict”. In this review we start by offering a brief description of what sexual conflict is and what the important variables are that shape the way in which it is expressed (and can be measured). We subsequently analyze the causes of sexual conflict following Tinbergen's four questions, with a special emphasis on the ontogenetic level, the latter with the specific aim to provide a more integrative view of sexual conflict and its evolution.

What Is Sexual Conflict?

Tregenza et al. (2006) noted that there is no clear or widely accepted definition of sexual conflict, pointing out that “biologists are often reluctant to

commit themselves to narrow definitions of concepts” in order to avoid limits in their thinking (p. 229), something that can be easily verified when looking at different publications on sexual conflict in which no definition whatsoever is provided. However, we consider that providing a definition, even if it is tentative and subject to future modifications as research progresses, is the very first step for constructing a solid theoretical framework in any research field. In the few papers on sexual conflict where a definition is adopted, authors most commonly cite what was put forward by Parker (1979, p.124): sexual conflict is “a conflict between the evolutionary interests of individuals of the two sexes.” Although this definition serves as a good starting point for evolutionary questions, we feel it is not completely accurate since males and females do not have themselves evolutionary interests as such but rather individual interests with evolutionary consequences. Moreover, the interest of males and females when they mate is actually the same: obtaining the highest benefits with the lowest costs (i.e., maximum fitness). One way to increase one’s reproductive fitness is by developing different strategies that increase the likelihood of being chosen by a given partner or by adopting high-quality mate-choice criteria, which result in what is called intrasexual competition for mates (e.g., males competing for access to a female) and mate choice mechanisms. Yet another possibility to increase one’s benefits while keeping costs low is to induce the other partner to increase his/her investment. Such a strategy will then imply a cost for the partner, who is expected to counter-adapt to avoid being manipulated. These two possibilities lead to two different types of conflict: one among subjects of the same sex, which is generally referred to as intrasexual competition, and the other one between the two mating partners, which represents actual sexual conflict. It is crucial to note here that the two can be intricately intertwined, making it difficult to disentangle them fully (see Brennan and Prum 2012).

Thus, sexual conflict is the disagreement over investment that ensues because males and females adopt or develop strategies that are only aimed to increase their own fitness but that imposes a cost

on the mating partner. In other words, what is beneficial for one is detrimental for the other. Such conflict stems from the unequal or differential investment in reproduction of a particular male and female when they mate. This differential investment is already seen at the very early stages of the reproductive cycle due to the fact that the cost of producing gametes is assumed to be different between males and females, which finds its origin in anisogamy (see Table 1; Schärer et al. 2012). Due to differences in gamete size, the production of eggs is generally considered to be more costly than the production of sperm, and consequently, for females, reproductive success is limited by their capacity to produce eggs, whereas for males, reproductive success is more dependent on their access to females (e.g., see Arnold (1994) for a review but see also Janicke et al. (2016) for a meta-analysis on the selection pressures suffered by males, which are stronger than those suffered by females, potentially equating the costs experienced by both sexes). This difference in the costs of gamete production entails a difference in the benefits obtained per unit of energy invested that does not allow males and females to reach their optimal reproductive fitness simultaneously (Parker 2006). As a result, any trait that increases males’ fertilization success will be selected even if such a trait implies a cost for their female partners. The conflict then arises because the strategies that males employ to increase the investment of females are actually decreasing the reproductive fitness of females. Of course, the development of manipulative mating strategies is not exclusive to males, as females also contribute to this conflict by evolving their own mechanisms that lead to increases in male investment and a reduction of their own costs (e.g., Chapman et al. 2003). To give one classic example, a male’s paternity success will be significantly increased if he manages to prevent the female he has mated with from remating with other males (e.g., via mate guarding). This will secure his paternity, but at the same time, it implies an important cost for the female in that she will lose future opportunities to mate with other males. Under that particular scenario, females are expected to develop other strategies

that will allow them to somehow avoid the costs of such mate guarding. This adaptation of the females would not benefit the males and would again lead males to counter-adapt and so forth. Hence, the conflict between the individual interests initiates a process of adaptation and counter-adaptation to the strategies employed by one sex and the other that, over time, results in a continuous evolutionary arms race between the sexes (e.g., see Koene 2012). It is important to note that there are some authors who have criticized this view and instead suggest that mating should be seen as cooperative rather than as a conflict (e.g., Cordero and Eberhard 2003). These authors claim that, for example, females actually increase their fitness from mating with males that are able to manipulate them because they will sire sons that will also be able to manipulate next-generation females (and the same would be true for males who mate with manipulative females). From this perspective, sexual reproduction can be viewed as a cooperative task where males and females have a common goal that is to obtain better-quality offspring. However, we will here stick to the term “sexual conflict” as it allows us

to refer to manipulative traits that are initially harmful for the other sex although they may become beneficial in the long run (see also Brennan and Prum 2012).

Who Is Involved in the Conflict?

Although sexual conflict arises from the different interests of males and females, it can involve more participants than just a male and a female. Generally speaking, it could be argued that as long as there is polygamy, more individuals than just the mating couple will be affected by sexual conflict. In the case of polygamous males, multiple mating can have different costs for the female. For example, males may be sperm-depleted, which could lead to a lower fertilization rate or they may reduce parental care (because they are busy somewhere else) compromising the survival of the offspring. Similarly, polyandry (i.e., a female mating with multiple males) is costly for males: the costs of producing sperm and other accessory gland substances will be high when considering that paternity will be shared with other males (see

Sexual Conflict in Nonhumans, Table 1 Definitions of important psychological and biological concept that we use in the text but that may not be familiar to readers of either field of research

Definitions	
Circular reaction	Repeated display of a basic sensory-motor schema (that animals are born with). It allows animals to interact with the environment and to satisfy their needs, but, as a result of repetition, the schema is modified, resulting into a new one. The new schema will again affect the way an animal interacts with and alters its environment, as well as the schema itself
Anisogamy	Size difference between the types of gametes; generally, females produce large gametes that are usually non-motile (eggs or ovules), and males produce smaller gametes that are often motile (sperm or pollen)
Accessory gland substances/ products/proteins	Products of (male) accessory reproductive glands, usually peptides or proteins. They can be transferred to the mating partner during sperm transfer (along with the sperm) or disassociated from sperm transfer (e.g., via injection using a specialized organ). These substances are also referred to as seminal fluid products/proteins (SFPs) when they are added to the sperm before transfer of the semen (i.e., sperm plus SFPs)
Allohormones	Substances, such as proteins and peptides, that are transferred between individuals of the same species and that induce a direct physiological response, bypassing sensory organs
Organic selection	Organic selection refers to the fact that each individual has the ability to accommodate to the new circumstances of the environment, contributing to its own selection. This is also referred to as the <i>Baldwin effect</i> (i.e., changes in behavior affect reproductive success and adaptation but it does not necessarily imply a change in the genome)

Parker and Birkhead 2013 for a review on polyandry). In this case sexual conflict is tightly related to intrasexual competition and mate choice, which does not only occur before mating but can also happen after mating (i.e., post-copulatory). For example, when a female mates with more than one male, sperm of different males will compete for the fertilization of the ova, and the female can exert a choosy role over the sperm received, reducing the benefits of some of the males she had mated with. This **cryptic female choice** can be inferred, for instance, by looking at paternity biases in her offspring or by looking at the differential reproductive investment that the female performs (see Chapman 2006 for a brief comment on this). One example of such cryptic female choice that leads to sexual conflict can be observed in the female decorated cricket (*Gryllodes sigillatus*). In this species the male transfers a spermatophore (an ampulla that contains the sperm) that is covered by a gelatinous substance called spermatophylax. The female detaches the spermatophylax from the spermatophore and eats it right after copulation has taken place. Once she has eaten it, she removes the spermatophore and thus sperm transfer is terminated. This allows females to bias paternity: the longer she takes to remove the spermatophore, the more sperm she accepts from the male, which is directly related to the male's paternity success. In a study conducted by Ivy and Sakaluk (2007), females of this species were allowed to mate two times with two different males that were either attractive or unattractive. When the second male they mated with was attractive, females retained the spermatophore for longer (i.e., they accepted more sperm) regardless of whether the first male they had mated with was attractive or unattractive. Females thus reduced the first male fitness just by accepting the spermatophore of the second male. This could also be seen as a female mate choice strategy that results in costs for the first male. The female would accept more sperm from the high-quality male because it is beneficial for her, and as a side effect, the first male will lose fitness. This example illustrates why sometimes it is difficult to establish clear boundaries between mate choice and sexual conflict.

Another situation in which more individuals are involved is that of **infanticide**. Infanticide usually takes place when a female is taking care of her offspring. In this situation the target of this harmful strategy is the offspring, sired by a different male, that the female is taking care of. By killing her offspring, the male increases its own reproductive success as it can shorten the interval to the next ovulation, and therefore he can induce mating responsiveness in the female (see Hrdy 1979 for a review on infanticide). An example of infanticide can be observed in a spider species, *Stegodyphus lineatus*. The female of *S. lineatus* guards her fertilized eggs in a sac for about 30 days, after which she opens the sac and the young hatch. Once the eggs hatch, she feeds her offspring by regurgitation and then she gets eaten by the spiderlings. Given the suicidal maternal care and the fact that encounters between a male and a female are very rare (one or two in their lifetime), when a male encounters a female that is guarding an egg sac, he will attempt to mate with her. To do so, males need to remove the egg sac from the female so that she is induced to re-lay eggs and remate. This is very costly for the female because even if she remates, the egg cluster size will be significantly smaller, and hence, her reproductive fitness will be significantly reduced. For this reason, females defend their eggs when they encounter a male (Schneider 1999, and references therein).

Finally, although until now we have discussed sexual conflict between males and females, sexual conflict also occurs in hermaphrodites (reviewed by Schärer et al. 2014; Koene 2016). Since hermaphrodites are both male and female, in order to distinguish between the two sexual functions, we will use the term "sperm donor" to refer to the male function, whereas "sperm recipient" will refer to the female function. In the case of hermaphrodites that take turns when mating (i.e., they are functionally both male and female but at each mating encounter then can only perform one of the two roles), a conflict will ensue whenever the two mating hermaphrodites want to adopt the same, and thus incompatible, role. This can lead to a situation in which only one of them performs the desired role, reducing the fitness of its partner.

Even if there is no conflict over the sexual role to be performed, sperm donors, as in separated-sex animals, will attempt to affect the female function of the sperm recipient. This can be done by means of accessory gland proteins that increase the sperm recipient's allocation to the female function (e.g., by inducing the sperm recipient to lay larger eggs). A clear example has been described in the great pond snail *Lymnaea stagnalis*, a simultaneous hermaphrodite that chooses roles when it mates. The snail that performs the male role transfers accessory gland proteins, among which LyAcp10 (called ovipostatin) that causes a delay in egg laying in the snail that performs the female role (Koene et al. 2010). This delay is followed by a higher investment per egg in snails that repeatedly received inseminations (Hoffer et al. 2012), which increases hatchling success (Hoffer et al. 2017) and thus overall fitness of the sperm donor. A more traumatic manipulation can also be found in banana slugs (*Ariolimax dolichophallus*), which have been reported to bite off the penis of the partner after copulation. Such a strategy seems to force the partner to allocate all its resources to its female function, preventing it from mating in the male role (Reise and Hutchinson 2002).

In short, sexual conflict results in costs or harmful consequences for the partner, but sometimes those costs are suffered by someone else, as it happens in the case of infanticide. Cryptic female choice can also reduce the reproductive benefits a male would obtain when the female mates with more than one male. Finally, although for a long time it was widely accepted that hermaphrodites would not experience sexual conflict, recent empirical research has now revealed that it does occur.

When Is There a Conflict?

The conflict between males and females over reproductive investment can occur at different levels. Here, we will focus on only four of these, namely mate access, paternity, egg investment and parental care, but see Kokko and Jennions (2014) for more. In some species **mate access** is already an important source of conflict even in the

absence of competitors. For example, the female alfalfa leaf-cutting bee (*Megachile rotundata*) actively resists mating with a male by kicking him with her legs and using abdominal thrusts to dislodge him. A female's success at avoiding mating represents a high reproductive cost for the male but is beneficial for the female as she avoids the costs of (superfluous) mating. On the contrary, a male's success at mating reduces a female's fecundity, longevity, and ability to forage (Rossi et al. 2010).

In species that mate more than once, another or a more attractive partner may be encountered. In such a situation, it would be interesting for both males and females to be able to mate again, but this would reduce paternity success of both the former and current mating partners, prompting a conflict over **paternity**. One way of preventing such a paternity cost is by mate guarding, which can be done either pre- or postcopulatory. For example, after mating, males of the moth *Achroia grisella* start signaling to attract other females, increasing the likelihood of engaging in a second copulation. However, because males have just mated, they need to produce new sperm and this takes several hours. In order to increase their paternity success, males copulate for several hours, while the new second ejaculate is being produced. These long second copulations represent a precopulatory mate guarding strategy because it prevents the female from mating with a virgin male and increases the paternity success of the male that performs such guarding. Indeed, when males perceive a male competition situation (i.e., another male competitor's song), the latency to start a second copulation is significantly reduced: they engage quicker in precopulatory mate guarding (Jarrige et al. 2016). Mate guarding can also take place after mating and a typical example of such postmating guarding strategies are mating plugs, which can, for example, be found in male bumblebees (*Bombus terrestris*). They transfer a sticky substance into the female sperm-receiving organ that reduces her willingness to remate (Baer 2003 and references therein). Bumblebees also make use of a more simple strategy to increase their paternity success. They engage in long-lasting copulations so that half of

the female's spermatheca (i.e., where the sperm are stored before fertilization takes place) is filled with their sperm (Baer 2003). Some other animals, like dragonflies, use sperm removal strategies to overcome conflicts over paternity. Their copulatory organs possess small spines that trap the sperm from previous mating encounters and that allow them to remove the other males' sperm from the females' sperm storage organ before transferring their own sperm (Córdoba-Aguilar et al. 2003). All the mentioned displays provide males with advantages since they reduce male-male competition and increase their paternity success; however, for females this is not necessarily optimal (see Brennan and Prum 2012 for a discussion on this). This again illustrates that intrasexual mate competition is highly linked to sexual conflict, blurring the boundaries between the two concepts.

Females can also reduce a male's paternity success by preventing males' sperm from reaching the eggs. For example, red jungle fowl (*Gallus gallus*) females expel males' sperm. Such a strategy can be of great advantage for reducing the costs of mating with a lower-quality male, as it would happen in the case of inbreeding. As shown by Pizzari et al. (2004), when females of this species were inseminated by a brother, the number of sperm that reached the eggs or that was stored in the female's sperm storage organs was significantly lower (no differences were observed in the amount of sperm that males transferred to their sisters or to the unrelated females). An even simpler method of discarding sperm is that of sperm digestion. For example, in many hermaphrodites the sperm that is received can either be digested in a specialized organ or stored for fertilization. In the land snail *Cornu aspersum* (formerly *Helix aspersa*), most – about 99% – is digested (Rogers and Chase 2001).

Another source of conflict between males and females is the offspring, and the first stage at which this conflict can be observed is that of **egg investment**. As previously described, in *Lymnaea stagnalis* the individual that performs the female role receives an accessory gland protein (LyAcp10) that induces a delay in egg laying. Such a delay seems costly for the sperm recipient

because its egg investment is increased and the number of offspring decreased (Hoffer et al. 2012), and, as a result, this may move the sperm recipient away from the optimal division of investment in current and future female reproduction (Hoffer et al. 2017).

In some species, both parents need to take care of their young as otherwise it would be difficult for the latter to survive. This particular situation leads to two different conflicts. One is over the amount of resources that each of the parents is going to invest in the current offspring, and the other is over the optimal moment they should stop investing in the current partner's offspring and divert their resources to new offspring (that could be sired by a different partner or not). There are a number of experimental studies in which the sexual conflict over **parental care** is assessed, especially in birds. To study this, researchers have experimentally manipulated the amount of parental investment performed by either the male or the female. In some cases, one of the parents was removed (which allowed to see if a single parent could provide the same amount of care that is usually provided by two parents), and, in some others studies, the care provided by one of the parents was reduced (e.g., by handicapping one of them). In a recently published meta-analysis on how sexual conflict is resolved in different species of birds (Harrison et al. 2009), it was shown that when one of the parents reduced its caring behavior in terms of food provisioning, the other one compensated by increasing its parental effort although it did not compensate fully. Concerning the moment a parent should stop investing in the current offspring and try to reproduce again, one of the cues an animal can use is partner attractiveness. The attractiveness of the current partner is an indicator of the quality value of the current offspring: the more attractive the partner is, the higher the perceived value of the offspring when compared to future offspring (that may not be sired by an attractive mate), and thus investment in the current offspring is expected to increase (see, e.g., Limbourg et al. 2004). An example of how longer or shorter investment in the current offspring is dependent on the partner's attractiveness can be seen in blue tits (*Parus*

caeruleus). The crown of blue tits presents a UV coloration that is different for males and females and that indicates sexual attractiveness in both sexes. In an experiment conducted by Limbourg et al. (2004), the coloration of the UV component was reduced by using UV-blocking chemicals during the nestling period (i.e., after mate choice had taken place). The results showed that females that had been paired with males of reduced UV coloration invested less in their offspring (they fed them at lower rates) than females that had been paired with non-manipulated males. Taken together, these studies on parental care show that when one of the parents reduces feeding or care-providing rates, this immediately exerts a reduction in the gains that the other parent obtains from having mated with him or her.

In summary, we have reviewed four of the possible reasons why males and females are in conflict. The first one is the act of mating in itself, where animals may not be willing to mate or they may prefer others as partners. The second source of conflict is paternity. Mating with more than one partner will increase genetic variation among the offspring, which can provide great advantages. Because sperm are relatively cheap to produce, males will benefit from fertilizing all the eggs produced by different females, whereas for females it would be more profitable to have their eggs fertilized by different males. The allocation of resources to the eggs once they are fertilized is another source of conflict between males and females, as well as the resources that each of the parents invests in raising the offspring when they need parental care. All these situations suppose a conflict for both parents that will be dealt with differently, as described below, depending on the particular way each species mates.

How Does Sexual Conflict Vary Depending on the Species' Specific Mating Strategy?

There is only one mating system in which sexual conflict would be expected to be more limited: **monogamy**. In situations in which there is strict monogamy, meaning that mating takes solely

place with a single partner, the traits that decrease the reproductive fitness of one sex will also cause a decrease in the reproductive fitness of the other sex (Hosken et al. 2001). Hence, males would be expected to be less harmful for females, and females would be expected to suffer more if they were to adopt a promiscuous strategy versus monogamy (Crudgington et al. 2005). However, the absence of sexual conflict in monogamous mating species can usually only be inferred, since absolute strict monogamy seems to be extremely rare, and even under strict monogamy, conflict can still arise over other mating aspects such as when to reproduce, how often or how many offspring to produce.

In some species, mating occurs in a very traumatic fashion: males cause injuries to the female's genital or non-genital structures. These injuries increase males' fitness for several reasons. For example, **traumatic mating** can allow males to better anchor to the female, but it also represents a more effective way of transferring accessory gland proteins that boost females' investment in reproduction (reviewed by Lange et al. 2013). This reproductive strategy is, for example, observed in the land snail *Cornu aspersum*. During courtship, snails of this species force a calcareous dart through the partner's body wall. Once they have "shot" each other, they mate simultaneously as male and female, transferring a spermatophore to each other. The mucus that accompanies the dart contains substances (called all hormones; see Table 1) that shorten the distance to the spermatophore-receiving organ (so the distance the sperm need to travel is shorter; Lodi and Koene 2016a) and close off the tract that leads to the sperm digesting organ (so less sperm gets digested), thereby increasing paternity success (reviewed by Lodi and Koene 2016b). Between species, the female function of land snails with love darts has counter-adapted to the manipulation of the dart by increasing the length of the duct through which the sperm travel (Koene and Lodi 2016b).

Another mating strategy is called **sexual parasitism**. An example of sexual parasitism is that of deep-sea anglerfishes, in which the males attach to the females either temporarily or permanently. In

Krøyer's deep-sea angler fish, *Ceratias holboelli*, the tissues of the male fuse with those of the female, and even their circulatory systems become shared. The male is then dependent on the female, and he fertilizes her via the circulatory system (Pietsch 2005). Sexual maturity of both sexes is only reached when the male attaches himself to the female. Interestingly, more than one male can be attached to a single female, a situation that would cause high male-male competition over the siring of the offspring. However, to date no studies have addressed how this sexual conflict is dealt with (which is not surprising given that the natural habitats of these animals makes such studies very difficult).

In some species, females display **sexual cannibalism**. Clearly, the male will not achieve any reproductive fitness when the female cannibalizes the male before sperm transfer. On the contrary, sexual cannibalism after copulation presents a (somewhat) more beneficial situation for the male in terms of reproductive success. But in either case, the female's reproductive strategy leads to a very high cost for the male since he loses any future reproductive opportunities. As a result, males can develop different strategies to avoid being eaten by the female. For example, in the web spider *Pisaurina mira*, males have evolved to wrap the female's legs with silk before mating with her, thus increasing his own mating success and survival (Anderson and Hebets 2016).

In many insects and spiders, males provide females with **nuptial gifts** in order to entice females to mate. A particular effect of edible nuptial gifts is that they also serve to prolong ejaculate transfer (e.g., Vahed 2007). For example, in the cricket *Gryllodes sigillatus*, successful copulation occurs after the spermatophore has been transferred to the female. As already reported, this spermatophore is attached to a gelatinous substance called spermatophylax that the female detaches from the spermatophore and eats right after copulation has taken place. Females will take a considerable time to eat the spermatophylax (about 40 min) after which they will remove and eat the spermatophore. When the spermatophylax quantity is small, females will

take less time to eat it and will remove the spermatophore sooner, diminishing the amount of sperm transferred and thus resulting in a lower rate of male fertilization success (Sakaluk et al. 2006). Contrarily, larger spermatophylax result in increased quantities of sperm transferred, leading to a higher proportion of eggs fertilized by that male (i.e., reduced sperm competition). Moreover, prolonged ejaculate transfer will also result in a higher transfer of (allo)hormonal substances (i.e., accessory gland secretions) that are known to reduce female mating receptivity (again reducing sperm competition) or to increase the rate of oviposition (increasing paternity success). Thus, accepting such nuptial gifts from the males implies several costs for the females, such as longer sexual refractory periods that prevent females from mating with other males, thus reducing the benefits that the female can obtain from polyandry (reviewed in Vahed 2007).

All the examples given in this section illustrate that sexual conflict is a constant but that the particular mechanisms that animals use to influence the mating partner vary from species to species. Together with the examples of the previous sections, this overview shows that males of different species try to increase their reproductive success via different strategies that are all aimed at increasing the likelihood of siring the female's offspring. These strategies range from preventing the female from mating with another mate, reducing her willingness to mate again, to increasing her investment in egg production. Sometimes they can even evolve to such extremes that result in physically injure to the partner, as illustrated by the case of traumatic mating. Likewise, in an attempt to maximize their own fitness and at the same time reduce the costs of mating, females have also evolved different behavioral (e.g., cannibalism) and physiological (e.g., sperm digestion) strategies to avoid mating or to bias paternity.

Causes of the Conflicts

In this section, we will look at the causes of sexual conflict following the scheme suggested by Nico

Tinbergen (1963) for the study of animal behavior. According to him, a particular behavior can be explained in terms of its causation (physiology), survival value (function), ontogeny (development), and evolution (phylogeny). We will provide examples of how sexual conflict can be addressed at each of the four levels, but since one of the main aims of this review is to emphasize how sexual conflict can be affected by experience, we will specifically focus on the ontogenetic aspects that underlie mating behavior and sexual conflict.

The main reason why we will focus at the ontogenetic level is that when considering the different aspects that affect evolution, behavior has long been recognized as one of the main driving forces (e.g., Baldwin 1896). Indeed, behavior and cognition are present in all daily aspects of an animal's life, from foraging to predator-avoidance and sexual decisions, and they can be a source of new and fast adaptations. Surprisingly, the role that they play in some of these domains has been widely overlooked, or even denied, and only very recently have researches started to pay attention to them (West-Eberhard 2003). Concerning sexual selection, some authors have begun to acknowledge that learning has significant implications for mate choice (Witte and Nöbel 2006) or for speciation through sexual selection (Verzijden et al. 2012). Sexual conflict is tightly linked to sexual selection and forms a very important factor that affects the evolution of male and female traits (e.g., Panhuis et al. 2001), but is exclusively explained in terms of genetic mechanisms (i.e., intra-locus and inter-locus sexual conflict; see Koene 2012 for these concepts). Neither in a comprehensive book (Arnqvist and Rowe 2005) nor in a recent edited volume (Rice and Gavrillets 2014) on sexual conflict was any special attention paid to the role played by the psychological aspects of behavior and cognition, while a recent chapter (Chapman 2015) barely skimmed the surface of this important topic within evolutionary psychology. For this reason, we would like to highlight the fact that psychological processes (attention, perception, motivation, learning, memory, and decision-making) are also at play in the context

of sexual conflict and that their study is of great relevance for shedding light on this field of research. Tinbergen used the term “ontogeny of behavior” to refer to the way in which an animal acquires knowledge or a skill (Tinbergen 1963, p. 423). Animals are born with simple and innate sensory-motor coordinations that guide their first experiences, but the outcomes of those experiences will affect the way in which the animal behaves in a circular reaction (see Table 1) that is in constant development (Piaget 1976; see Sánchez and Loredó (2007) for a more detailed definition of this Baldwinian effect). As a result, any behavior performed by an organism is affected by experience, and not solely determined by instincts. The responses that every individual constructs based on its sensory-motor coordinations and experience constitute new learned adaptations, skills, or behavioral responses that have a positive effect on the survival of organisms, as they allow animals to better adapt to the changing demands of the environment or even to certain genetic variations that constrain their survival. This has clear implications in evolutionary terms, and for this reason, the analysis of psychological processes that are involved in the construction of new adaptive habits is of great importance despite the fact that they are not themselves directly determined by the genes (reviewed by Sánchez and Loredó 2007). Although Tinbergen explicitly referred to learning when talking about ontogeny, it must be taken into consideration that learning is intrinsically linked to other cognitive processes (such as attention, perception, or decision making) in such a way that experience affects them and they affect experience. Because of this, when examining the ontogeny of behavior, we will not only address the importance of learning but also of other cognitive aspects that are relevant for sexual conflict.

Importantly, as will become apparent, these four categories are not mutually exclusive, and none of them, when analyzed in isolation, provide a definite answer to sexual conflict (or any other question), but, when taken together in an integrative perspective (see Fig. 1), they can serve to reach a comprehensive understanding of sexual conflict.

Sexual Conflict in Nonhumans, Fig. 1 Schematic illustration of the four questions of Tinbergen applied to the field of sexual conflict. Sperm donors (males) are endowed with physiological mechanisms (causation) that affect sperm recipients' (females') reproductive resource allocation and vice versa. However, physiological responses to reproductive stimuli can be affected by animal's experiences over their lifetime (ontogeny). The way in which sperm donors and recipients deal with sexual conflict situations has an important effect on their reproductive success (survival value) that affects the way in which reproductive

traits evolve (evolution). Importantly, as depicted in the figure, all four questions are interlinked, and thus, an integrative study of the four of them is important in order to comprehensively understand sexual conflict. It is also useful to note that causation and ontogeny topics are generally addressed with "how?" questions, while survival value and evolution with "why?" questions. Moreover, it is useful to realize that causation and survival value focus on the here and now, while ontogeny and evolution look at changes over time

Causation

Causation essentially refers to the physiological mechanisms that underlie a given response, and one example of how physiological responses affect sexual conflict can be seen in the already mentioned case of the land snail (*Cornu aspersum*). In this species, dart shooting enhances sperm storage as it prevents sperm from being digested. However, the female function of the snail that receives the dart and the mucus that covers the dart can counteract this attempt of manipulation by means of sperm digestion, which drastically reduces paternity success of the sperm donor (Rogers and Chase 2001, reviewed in Lodi and Koene 2016a). As a result, these two physiological responses create a constant arms race, which is also commonly seen in separate sexed species.

Survival Value

When studying the function of specific traits of males and females that affect reproductive fitness, one essentially addresses the question of why this has evolved (what is the survival value?). From the neo-Darwinian or modern synthesis perspective, survival value or fitness is often inferred by

looking at genetics: if a trait contributes to an animal's survival and reproduction, it will be selected and passed on to the next generation. Although this parallelism between survival value and genetics is oversimplified, for our purpose it suffices here as it allows us to illustrate how survival value can be measured.

Drosophila melanogaster provides a great model for the genetic measurement of survival value. In this species, different accessory gland proteins affect sperm competition among males. One of them is Acp36DE, a protein that binds to sperm and that enters into the spermathecae of the females, facilitating sperm storage. Genetically modified males that cannot produce Acp36DE transfer normal amounts of sperm to the female when copulating, but their sperm are not accumulated in the sperm storage organs of the female. Because of this, no displacement of previous males' sperm takes place and a lower fertility rate is achieved (Chapman et al. 2000), thus revealing the adaptive (survival) value. Likewise, mutations in a different protein (Acp26Aa, called ovulin) impair the capability of inducing females to lay eggs. This protein has been shown to be responsible for the stimulation of the ovary to

release oocytes. Females that were mated to mutated males that were not able to produce this protein laid significantly fewer eggs than females that were mated to wildtype males (Heifetz et al. 2000). These two studies show how sexual conflict strategies can be addressed at a genetic level and how sexual conflict is of great importance for animals' survival or fitness.

Ontogeny

Throughout this review we have been talking about mating as if it was a simple behavioral response or action that all animals can display automatically or innately (i.e., determined by physiological or genetic aspects). Nevertheless, cognitive processes are also involved. For copulation to happen, "animals must be able to respond to hormonal and neurochemical changes that signal their own sexual desire and arousal, to identify external stimuli that predict where potential sex partners can be found, to actively seek out or work to obtain sex partners, to distinguish external chemosensory cues or behavioral patterns of potential sex partners from those that are not sexually receptive, and to pursue desired sex partners once sexual contact has been solicited. At each step, animals depend not only on the perception of their own internal state, but on the accurate prediction of external events. Such predictions are based on experience, both with the relation between external and internal stimuli and the relation of these stimuli to their sexual consequences" (Pfaus et al. 2001, p. 291). In this description of mating, many psychological processes are involved (e.g., motivation, perception, identification or even prediction). Such processes and the responses that animals display, as claimed by these authors, are mediated by their previous experience, in which learning and memory play a crucial role.

One way of experimentally measuring the effect of learning in a sexual conflict situation is by means of *associative learning*, which is one of the most thoroughly studied forms of learning. As described by Pavlov (1927/2003), this type of learning takes place when an initially neutral stimulus (e.g., an acoustic stimulus) is presented together with a biologically relevant stimulus

(e.g., food). When the neutral or conditioned stimulus (CS) is repeatedly paired with the meaningful or unconditioned stimulus (US), animals start displaying a conditioned response (CR) in the presence of the CS alone. In Pavlov's classical experiment, the sound produced by a metronome (CS) was paired with food powder (US) that was fed to the dogs. After several learning trials, dogs started to salivate (CR) when exposed to the metronome alone, without needing the food to be present.

This type of learning has been shown to be adaptive for animal reproduction as well as it can increase their reproductive fitness at different levels, and one of the first experiments to show this adaptive value was that of Karen Hollis. In her most influential work, she exposed male blue gouramis (*Trichogaster trichopterus*) to a light (CS) followed by either the presence of a male or a female (US). After training, animals were allowed to interact in a test that was signaled by the CS. Animals of the Pavlovian group were able to predict their encounter with a female and responded less aggressively to the females. They delivered significantly less bites compared to the males that were not able to rely on the CS to predict the presence of the female, and they also spent more time in the courtship appeasement posture than the control males (Hollis 1999). This training did not only result in less aggressive behavior toward the female, but it also increased male blue gouramis paternity success: Pavlovian males took less time to induce spawning in the female, and they also produced significantly more offspring than control males. On the contrary, when the lightning of the red light was used to signal the presence of another male, the experimental males increased the number of aggressive responses (frontal displays, bites, and tail beatings) toward the intruder (Hollis 1999). This work demonstrates how Pavlovian conditioning in the blue gourami can help in the identification of a conspecific (male or female) as well as in the selection of the right behavioral repertoire to be displayed at a given encounter (courtship or aggressive behavior). Furthermore, these results show that associative learning had a great impact in terms of sexual conflict: it reduced the level

of male-female sexual conflict (i.e., it induced a faster and higher spawning response in the female). This in turn increased the reproductive and paternity success of the learning males as exhibited by the large amount of offspring sired by the males who were able to use the red light as a predictor of the female.

Comparable results have been observed in the Japanese quail *Coturnix japonica*. In a study conducted by Domjan et al. (1998), a context was used as the CS to signal a mating encounter (US) for the males in the learning group, whereas males of the control group were exposed to the same stimulation but in such a way that they were not able to associate both events. Males in the learning group produced larger ejaculates and a larger number of spermatozoa compared to the control group. These results show how being able to predict a mating encounter can increase sperm competition-related physiological responses in the male Japanese quail while increasing the male's chances of siring a higher proportion of the female's eggs. More notably, the effect of Pavlovian conditioning over paternity success can go even beyond the production of sperm. As Adkins-Regan and MacKillop (2003) reported, the number of fertilized eggs significantly increased when either the male or the female had been subjected to Pavlovian conditioning, which also shows that physiological resistance responses of females can be modified depending upon the females' ability to predict a mating encounter. This type of training can also provide advantages in those situations in which there is male-male competition. This was experimentally tested in a study in which two different males had the opportunity to copulate with the same female, but only one of them received classical conditioning training. In the test, both males copulated with the female and whether the learning or the control male copulated first or second with the female was counterbalanced. The male who had been subjected to classical conditioning training was not only quicker at mating but also sired significantly more offspring (78% vs. 28% instead of the usual 50–50% rate that is found in this species) regardless of who mated first with the female (Matthews et al. 2007). Notwithstanding, how

such male-driven paternity bias can affect female fitness remains unexplored (i.e., the learning male is not necessarily the best one in terms of genetic quality).

Taken together, these studies demonstrate that Pavlovian conditioning can facilitate several stages of the mating sequence by somehow reducing the different sexual conflicts that may be present. The reduction of sexual conflict can be achieved by a change in the behavioral response, as in the case of the blue gourami: increased or decreased aggressive or courtship responses. Importantly, such behavioral changes had an effect of significance on the spawning response of the female. Likewise, learning mediates the physiological responses of the Japanese quail as manifested by the increase of sperm production, fertilization rate, or even paternity rate.

However, not all the experience that affects sexual conflict is acquired through associative learning and experience does not necessarily lead to a reduction of the sexual conflict. Experiments with guppies (*Poecilia reticulata*) have shown that when females are allowed to choose between two different males, they consistently prefer the same given male but that this preference can be reversed if they are allowed to observe a second female near the non-preferred male (Dugatkin and Godin 1992). In this scenario, females are conducting two different perceptual assessments: they are evaluating the quality of the two males but also the quality of the model female. Indeed, it has been observed that guppy females will choose the same male an older female has chosen, but not the one chosen by a younger female (Godin et al. 2005). In this case, age-dependent *imitation* would actually increase sexual conflict in terms of female-female competition. In a situation in which there are several females that select the same male, the male might experience sperm depletion, thus reducing the benefits the female would obtain.

In some of the examples already mentioned in the previous sections (e.g., the males of the moth *Achroia grisella* who reduced the latency to their second mating when they heard another male's song; the female of the red jungle fowl that was able to get rid of sperm coming from a brother, or

the birds who reduced their investment in their offspring as a consequence of a reduction of their partners' attractiveness), it is clear that animals assess the quality of their partners and invest accordingly. In all these examples, animals perceive a situation, assess the information they have processed, and make a decision on the quality of the mate. However, in none of these examples was the role of experience examined, and one could feel tempted to attribute the responses observed in each case to instincts or physiological mechanisms. In turn, studies in which learning has been shown to be relevant (see below) invite us to be cautious about such attributions.

Within the mating sequence, psychological processes have been shown to especially affect mate access, which is the first level at which sexual conflict is observed. As just illustrated, mate choice can be affected by learning from other conspecifics, but it can also be modified upon individual experience. For example, mate choice preference can be determined by simple exposure to a given phenotype (i.e., *familiarity*). Female wolf spiders (*Schizocosa uetzi*) do not display any innate preference for two extreme male phenotypes (brown or black pigmentation of a portion of the tibia of the forelegs) when they had not been exposed to either phenotype as subadults. However, they did show learned preferences after having been exposed to one or the other phenotype before reaching maturity: they were more likely to mate with the male of the familiar phenotype and also more likely to cannibalize the male that had the unfamiliar phenotype (Hebets 2003). This demonstrates the impact that learning can have on a sexual conflict situation, with extreme consequences for the males. In naturalistic situations, this conflict is reduced because males mature earlier than females and court them while they are still in their last stage before reaching maturity. This allows females to learn about the different male phenotypes so that the likelihood of mating with a particular phenotype increases and the chances of cannibalizing the male of that familiar phenotype are reduced.

For other species, familiarity is not enough and successful mating provides animals with

cumulative experience that shapes the way sexual conflict is dealt with, as it occurs in the Pacific field cricket (*Teleogryllus oceanicus*). In this species males produce two songs, a short-range one and a long-range one, the long-range ones being the most preferred by females. Nonetheless, it was experimentally shown that if females mated with an unattractive male (short-range song producer) and on the following day they encountered another unattractive male, in this second mating, females took less time to mount males (which signals female's willingness to mate), and they also retained this second male's spermatophore for longer (Rebar et al. 2011). The longer retention of the spermatophore correlates with the amount of sperm that is transferred and therefore paternity (see above), so, in this situation, females' previous experience would reduce sexual conflict with the second mating male.

All the examples mentioned above show that mate choice is not innate but a cognitive process that starts with the detection and perception of the mate (or of a model) and that it also implies an evaluation of the processed information as well as a decision-making process that is influenced by different sorts of past experience (Ryan et al. 2009). The outcome of this complex series of processes is going to affect one of the most important decisions that animals make in terms of reproduction, and it will also have important consequences in terms of sexual conflict. Based on the experiments reported, learning and cognition affect sexual conflict at the level of mate choice and paternity success (as shown in the case of the female crickets that retained the spermatophore for longer), but it can also have major implications for the offspring. In several studies it has been observed that parents' investment in their offspring varies according to their mate preferences. For example, in a study conducted with house mice, male preferences between two females were assessed before pairing half of the males with their preferred females and the other half with their non-preferred females. The litter size and the number of offspring that survived to the reproductive age (among other variables) were greater when males were allowed to mate with their preferred female than when they had to

mate with their non-preferred female (Gowaty et al. 2003). Similarly, female canaries of the species *Serinus canaria* allocate different amounts of testosterone to the eggs they laid depending on the attractiveness of the males' song to which they had been exposed. They allotted more testosterone to the eggs they laid when they were exposed to attractive male songs than when they were exposed to unattractive songs. This difference in the allocation of testosterone leads to hatching asynchrony that in turn affects the survival of the offspring, so the male whose offspring has received less testosterone will see his parental success significantly reduced (Gil et al. 2004). These results certainly show that there is an ongoing assessment of the quality of the partner and that such evaluation has important consequences on the total fitness of both males and females. In both examples given, males and females were investing less in the offspring they had sired, thus increasing the partners' costs. Interestingly, so far there are no studies that test the possible changes in offspring number or viability after preference for a given mate has been altered as a result of learning.

In short, learning and other cognitive processes are involved in sexual conflict situations. They can affect sexual conflict at, at least, two of the four levels: mate access and paternity. Concerning egg investment and parental care, it is certain that animals do assess their partner's quality to invest accordingly; however, the role of learning still needs to be more convincingly explored and integrated into our thinking. Thus, although ontogeny exerts an important effect, it must be acknowledged that a systematic evaluation of how animal psychology affects sexual conflict is still needed in order to fully appreciate the role that ontogeny plays in this domain.

Evolution

Phylogenetic analyses can shed light on the evolution of genetic, physiological, or behavioral responses that we observe in the field of sexual conflict. This type of analyses would allow us to identify the preceding events that have

contributed to the occurrence of such adaptations. For example, regarding physiological traits that are involved in sexual conflict, phylogenetic comparisons have revealed how males and females have developed adaptations and counter-adaptations to overcome sexual conflict. An example of this can be observed in male seed beetles (Coleoptera: Bruchidae), who possess spiny genitalia that injure the wall of the female copulatory duct. This trait is thought to provide benefits to the males as it allows them to better anchor themselves to the female during copulation and seems to also transfer accessory gland proteins (Hotzy et al. 2012). However, the presence of spines on males' genitalia imposes a cost for the females, and a comparative study of the male and the female genitalia of three different species of seed beetles has shown that, as males developed more harmful genitalia, females counter-adapted by evolving a more resistant copulatory tract, protected with thicker connective tissue (Rönn et al. 2007).

Regarding the phylogenetic analyses of behavioral responses, studies are not very abundant, but one example can be found in the diving beetles (Coleoptera: Dytiscidae). In this family, females of two different species (*Rhantus binotatus* and *Dytiscus alaskanus*) have been observed to exhibit behavioral mating resistance (rapid and erratic swimming and attempts to dislodge the male by driving him into the substrate or against objects). In contrast, females of two other species (*Ilybius gagates* and *Neoporus undulatus*) do not show any resistance behavior when males attempt to mate with them. The behavioral resistance response seems to have coevolved as a counter-adaptation to long-lasting matings: the two species that do not resist male mating attempts take shorter to mate than the other two (Miller 2003 and references therein). However, no intermediate stages have been described so far, so this analysis remains inconclusive.

Finally, species' general mate preferences have been reported to also have an evolutionary origin as it has been observed in the platyfish preference for long-sword males. Swordless platyfish are thought to be more ancestral than swordtails, and female preference for the morphological trait

has been suggested as a pre-existing bias that shaped the evolution of the genus *Xiphophorus*. Swordtail females of two species that do not possess swords (*X. maculatus* and *X. variatus*) display clear preference for males that have artificially longer swords than normal males. Moreover, the exact same pattern of results was observed in females of a sister genus (*Priapella*) that do not possess swords at all. These results indicate that female preference for a sword-bearing male had to arise in an ancestor of the two genera (Basolo 1995).

In summary, phylogenetic analysis can help us to better comprehend the evolution of morphological, physiological, or behavioral traits that are involved in sexual conflict. However, as at the level of ontogeny, more studies that analyze the evolution of the aforesaid traits are needed for a complete understanding of sexual conflict.

Summary and Concluding Remarks

While the boundaries and definition of sexual conflict are still a matter of debate, in this review we have defined it as a consequence of the differential investment in reproduction of males and females (or the sperm donor and recipient in the case of hermaphrodites). This differential investment leads to more or less harmful mating strategies that can be displayed (at least) at four basic different levels: mate access, paternity, egg investment, and parental care. The participants involved in a sexual conflict scenario and the general strategy that allows overcoming the sexual conflict will vary depending on the level at which sexual conflict takes place and the species under study. When the sexual conflict is over mate access, animals can harass their mates or even cannibalize them. This immediately implies mate-avoidance responses or the development of different choice criteria by the individual that is competed for (usually the female). When the conflict is over paternity, strategies such as mate guarding, cryptic female choice, sperm digestion, sperm removal, or accessory gland proteins will be used to influence the partner's investment or to avoid

being manipulated. Seminal fluid proteins are also important when there is a conflict over egg investment, just as some other resource allocation mechanisms that can be displayed by the females (e.g., time of spermatophore acceptance). Finally, when the conflict is over parental care, a reduced investment in terms of feeding or protection can be observed among some animals, especially birds.

The particular way in which sexual conflict takes place and is dealt with at each level will strongly depend on the mating strategy of the species of focus (e.g., male spiders that wrap females to avoid being cannibalized and to increase paternity success). All the mentioned adaptations that animals have developed to increase the partner's investment lead to counter-adaptations on the other sex. It is for this reason that sexual conflict plays a fundamental role in evolution. Importantly, behavior is a ubiquitous component of animals' lives; however, the way in which psychological processes shape how sexual conflict is dealt with has been widely overlooked in the literature on sexual conflict. The studies reviewed in the preceding show how different psychological mechanisms, especially learning, affect the investment of males and females in reproduction, reducing or increasing it.

Analyzing sexual conflict in terms of Tinbergen's four questions, especially in terms of ontogeny, has allowed us to understand sexual conflict and its role in evolution in a more comprehensive way. Notwithstanding, caution should also be taken when doing this, for two main reasons. The first one is that although it might seem that the four questions about behavior are independent from one another, they are fully interlinked (sometimes overlap), and all contribute to a full explanation of a behavior (Tinbergen 1963; see also Fig. 1). The second one is that, due to the current focus of genetics as the causal factor of any aspect of an animal's life, it has been somehow implicitly accepted that Tinbergen's four questions are hierarchical; being changes in the genes that causes changes in the physiological response, what in turn allows animals to develop behavioral changes to finally cause phylogenetic changes that lead to evolution. As a consequence

of this, ontogeny has not received the deserved attention from an evolutionary perspective, or, if it has, it has been reduced to genetics. Indeed, conventional thinking considers that evolution is solely gene-mediated and behavior is very often also explained in terms of a genetic trait that can be selected upon (see, e.g., Gottlieb 2002). According to this perspective, all the possible behaviors an animal can display are encoded in that animal's genome, and if a given behavior leads to successful adaptation, it will be passed onto the offspring of that animal until it becomes a common trait (i.e., instinct) among a given population. Conversely, from the perspective of organic selection (see Table 1; Baldwin 1896) and EvoDevo, the *ability* to produce a behavior or a response in itself can become common due to a genetic change but not the adaptive evolutionary response per se (e.g., a behavioral innovation, such as the use of a tool, can become general within a group or population and be maintained along generations through social influence resulting in adaptation but not in evolution; West-Eberhard, 2003). Behavior and physiology are the two most flexible, faster, and reversible responses animals can display in a changing environment situation. They allow animals to express a novel phenotype, increasing the adaptation and the accommodation of the phenotypic change, but such adaptation and accommodation of the phenotype does not necessarily imply a genetic change. Like any other advantageous phenotypic variation (e.g., morphological variations), behavioral changes that increase adaptiveness will also be selected, but they will not be necessarily inherited (Sánchez and Loredó 2007; West-Eberhard 2003). Because of its high level of flexibility and its fundamental role on adaptation, behavior has long been recognized as a leading factor in evolution by some authors (Baldwin 1896), but its importance as such has only started to receive attention very recently. Experimental work like that of Karen Hollis in the blue gourami or that of Michael Domjan in the Japanese quail showed how associative learning (a change at the ontogenetic level) does actually have a major effect in the physiological responses involved in

reproduction. There is also experimental evidence from the field of epigenetics that shows that changes at the ontogenetic level can have important effects not only at the physiological but also at the genetic level (it can affect gene expression). This evidence questions the general assumption of a one-way genetic causation mechanism, and it contributes to the growing body of evidence on the connections between the different levels of causation (as depicted in Fig. 1) as well as to the acknowledgment of behavior as a crucial factor in evolution. Again, it must be emphasized that behavioral responses are not a genetically driven display. Behind any behavior that we observe, psychological processes such as perception, learning, memory, or decision-making are constantly present. They are the mechanisms that allow animals to interact with and to adapt to a changing environment. For this reason, whether our aim is to understand foraging, predator-avoidance, or sexual conflict, an integrative approach in which psychological processes and ontogeny are considered must be adopted. This does not deny the importance of genetics, but a complete picture of animal evolution will only be achieved if the different levels of analysis are fully integrated. In this work we have tried to provide a more integrative overview of sexual conflict by gathering examples of the four levels as a first step to a full and comprehensive understanding of sexual conflict and its evolution, although as noted in different parts of the manuscript, more work needs to be done to achieve this goal.

Sexual Conflict Theory (Middle-Level Theory in Evolutionary Psychology)

Joseph A Camilleri

Westfield State University, Westfield, MA, USA

Definition

Intraspecific selection that occurs when an adaptive trait in one sex comes at a fitness cost to the other sex, which creates a condition for antagonistic counter-adaptations to evolve.

Introduction

Sexual conflict refers to intraspecific selection that occurs when an adaptive trait in one sex comes at a fitness cost to the other sex, which creates a condition for antagonistic counter-adaptations to evolve, sometimes appearing like an arms race.

Sexual conflict occurs in one of two ways: intralocus and interlocus sexual conflict. *Intralocus sexual conflict* is when a trait is expressed in both sexes (i.e., allele variation occurs at the same locus), but fitness outcomes of the trait for each sex are different. An example of intralocus sexual conflict among humans is height – the relationship between height and number of offspring is curvilinearly related among men, but negatively related among women. Specifically, shorter height is associated with more offspring among women and fewer offspring among men, and average height is associated with more offspring among men and fewer offspring among women (Stulp et al. 2012). *Interlocus sexual conflict* is when different traits from each sex have conflicting interactions (i.e., alleles from different loci are in conflict), creating the possibility of agonistic coevolution. A common example comes from water striders where female copulatory resistance and male forced copulation represents a conflicting interaction. Sexual conflict may also result in palliative adaptations when sexual conflict produces collateral harm (harmful side effect of the trait that may impact both sexes). Though much of the literature has focused on nonhuman sexual conflict, this review will outline how sexual conflict has been applied to human psychology.

History

Sexual dimorphism was initially understood as a function of female mating preferences resulting in either indirect reproductive benefits (see ► [Fisher Process](#) or ► [Good Genes](#)) or direct reproductive benefits, such as receiving more resources or acquiring a mate who invests in their offspring (reviewed in Chapman et al. 2003). Sexual conflict is an alternative model that views sexual dimorphism as a cause or consequence of conflicting traits. Prior to Parker's formal articulation of sexual conflict theory, a few scholars had similar insights. Williams (1966) elaborated on R. A. Fisher's early suggestion of this idea by describing how a conflict between female choosiness and male dishonest signaling creates

an “evolutionary battle of the sexes” (p. 184). Trivers (1972) later described how sex differences in parental investment influences mating behavior: high parental investment is associated with being more selective in a mate whereas low parental investment is associated with greater competition for acquiring mateships. Such a scenario suggests there are conflicting interests between the sexes. Dawkins (1976) also suggested that if parent-offspring conflict occurs when they share 50% of genes, then conflict between mates should be much higher.

Sexual conflict was formalized by Parker (1979), who provided the most thorough investigation of the topic by using mathematical modeling to explore conditions and the extent to which sexual conflict could occur and by reviewing species that likely exhibit forms of conflict. Since Parker's seminal work, the concept of sexual conflict has received considerable attention, challenged traditional explanations of cooperative breeding, been widely applied across taxa to understand sex differences in physical and behavioral traits, and used to understand speciation (Parker and Partridge 1998), sperm competition (Stockley 1997), mate choice (Gavrilets et al. 2001), sexual coercion (Muller et al. 2009; Watson-Capps 2009), aging (Bonduriansky et al. 2008), among others. For reviews of sexual conflict in the nonhuman animal literature, see Arnqvist and Rowe 2013; Chapman et al. 2003; Parker 2006; Stockley 1997; Tregenza et al. 2006.

Middle-Level Theory in Evolutionary Psychology

More recently, sexual conflict has been applied to human psychology. Sexual conflict can be understood as a middle-level theory because it explains how sexual selection applies to a particular domain; it explains both the causes and consequences of traits that confer unequal fitness between the sexes. Though intralocus sexual conflict (see [Intralocus Sexual Conflict](#) section) has been applied to humans, such as conflict over height (Stulp et al. 2012), most psychological traits are addressed by interlocus sexual conflict

(see [Interlocus Sexual Conflict](#) section). Although much of the reviews have focused on applying sexual conflict to preexisting data and research, studies directly testing the application of sexual conflict theory to humans has been scarce. To date, only a few studies have been published that tested for the presence of intralocus sexual conflict in humans.

Intralocus Sexual Conflict

Intralocus sexual conflict occurs when a trait is expressed in both sexes but is beneficial to one sex and costly to the other. For example, a preference for indiscriminate sex would benefit men, but the same trait among women would be costly because of high investment in offspring with nonpreferred traits. Likewise, choosiness among women would benefit them by ensuring reproductive success through mate quality, but this same trait among men would be costly because it would reduce mate number. Only a few empirical studies have directly tested hypotheses informed by intrasexual sexual conflict among humans.

Garver-Apgar et al. (2011) demonstrated how men with more physically masculine traits had a higher mate value than their sisters, that estrogen was associated with greater mate value for women relative to their brothers, and that testosterone was associated with greater mate value for men relative to their sisters. These findings suggest that genes that code for either more masculine or more feminine traits benefits one sex while coming at a cost to the other. A similar study looked at facial masculinity and attractiveness: not only was masculinity correlated between male-female twin and sibling pairs, but there was a negative correlation between brother masculinity and sister attractiveness, though masculinity was not associated with attractiveness among men (Lee et al. 2014).

There is also evidence for intrasexual conflict over height in humans: amongst shorter male-female sibling pairs, females had more reproductive success, whereas the opposite was true for average height pairs (Stulp et al. 2012). This study more accurately used direct measures of reproductive success, rather than perceived

attractiveness (which should correlate with reproductive success or one's mate value).

Sexual conflict theory provides interesting insight into the evolution of female mating resistance by questioning whether it functions to screen potential partners or functions by reducing the costs of multiple matings (costs include time, energy, exposure to risk for injury, infection, toxins, reduced parental investment, etc., see Gavrilets et al. 2001). Though no clear answer has emerged, this example shows how sexual conflict can be used to generate new or competing hypotheses about the evolution of certain traits (Chapman et al. 2003). Similarly in humans, women's "choosiness" has been suggested to evolve through sexual selection to screen for potential mates, though such a trait could be a response to the costs of multiple mateships pursued by men or could even be a source of conflict towards men (choosiness is costly to men's optimal strategy of mate number/frequency). Still, a large amount of empirical and theoretical work is needed to understand how female mate choice and mating resistance can be explained through intralocus sexual conflict (Arnqvist and Rowe, book; Chapman et al. 2003), and although applications to humans are being proposed (e.g. Buss 2017), direct empirical tests are needed. Still, since humans meet many of the conditions that give rise to sexual conflict, such as variance in mate quality along with sex differences in reproductive rate (Arnqvist and Rowe 2013), intralocus sexual conflict may provide insight into the evolution of human mate choice.

Interlocus Sexual Conflict

Interlocus sexual conflict is when different traits in each sex are in conflict. Much of the psychological literature on interlocus sexual conflict focused on theoretical possibilities – how sexual conflict *could* apply to humans (Buss 2017; Mulder and Rauch 2009; Shackelford and Goetz 2012), and draw from supporting empirical work, but do not directly test for interlocus sexual conflict. Though terms sometimes vary, they generally categorize interlocus conflicts based on when

they occur: before mating (i.e., precopulatory or before sperm transfer), during mating (i.e., in copula or during and after sperm transfer but before conception), and after conception (post-conception, after birth; see Koene 2012; Shackelford and Goetz 2012).

Sexual Conflict Before Mating

Before mating, these are actions towards an opposite sex target that increases the probability of mating, but such actions are costly to that target. In other species, infanticide has been used as an example of this (Koene 2012). There is evidence to suggest how infanticide by males in some species functions by ceasing lactational amenorrhea and speeding up the time a female can mate with him. As Palombit (2015) reviewed, more recent research considered female counter-strategies to such conflict, including multi-male mating for paternity confusion (with a male counter-strategy of recognizing kin among multiple pups), female aggression as a deterrent, social isolation, building social coalitions, and social monogamy. Sexual conflict is an unlikely explanation for infanticide among humans because women are more likely than men to commit infanticide, and its prevalence is quite rare.

Sexual conflict could arise outside pair-bonded individuals when there are sex differences in optimal mating strategies (i.e., there is a conflict between men's interest in mating frequency and women's choosiness in mating partner). Conflict could still arise within pair-bonds when optimal reproductive rates differ (women may want a longer interval between children, whereas men may prefer a shorter interval), or when one partner pursues extra-pair mating.

Sexual deception and anti-deception have been cited as a source, and response to, conflict prior to mating (Buss 2017). Men may use sexual deception by displaying false signals of relationship commitment and love, whereas women could use sexual deception through false signals of sexual interest to secure resources, while both sexes could use sexual deception by falsely advertising their mate value. These sources of sexual conflict

are predicted to have led to antagonistic counter-strategies, such as anger and the ability to detect cause of deception.

Sexual coercion, which are actions that diminish female choice in mating (see Muller and Wrangham 2009), seem to meet the criteria for sexual conflict before mating among humans. These acts include herding (aggressive separation of women from other men), sequestration (aggressive removal of women from their social group), and harassment (persistent sexual pursuit until female capitulates or flee) that function to prevent extra-pair copulations. They benefit the male coercer by increasing his probability of mating while being costly to females due to restricting their mating options, such as offspring interval or extra-pair copulation.

Sexual Conflict During Mating

Sexual conflict during mating occurs during or after sperm transfer but before conception. There is a growing number of topics that may be relevant to sexual conflict during mating, such as orgasm, cryptic female choice, nuptial feeding, semen and vaginal chemistry, forced copulation and rape, intimate partner rape, and sexual cannibalism (see Shackelford and Goetz 2012).

The specific costs and benefits of traits during mating have been directly tested in nonhuman species. Fruit flies, for example, have been studied extensively. There are numerous costly effects of male accessory gland products that increase male reproductive success through improving the chances of successful sperm competition (Arnqvist and Rowe 2013), but are costly to females. These costs include decreasing female attractiveness to other males, reduced sexual receptivity, and increasing egg production.

In humans and other species that form pair bonds, a likely source of conflict during mating is cuckoldry risk, defined as the increased probability a female partner has an extra-pair copulation. Under such a scenario, females may benefit from offspring with better genes, but such actions come at a reproductive cost to their male partner, whose resources unknowingly go to unrelated

offspring. Considering cuckoldry incurs a steep cost to males, several counteradaptations to minimize cuckoldry risk may have evolved. These counteradaptations include various sexually coercive tactics, such as sexual harassment and intimate partner rape (see Camilleri 2012; Camilleri and Quinsey 2012). These actions are hypothesized to function by minimizing the risk of cuckoldry by engaging in sperm competition (i.e., sperm from multiple males within one reproductive cycle compete for insemination). Intimate partner rape creates a new source of conflict to females, whereby insemination may occur from a non-preferred male, or incurring physical injury. Several studies have linked cuckoldry risk with intimate partner violence and sexual coercion. Indirect preventative actions could also have evolved, such as aggressively herding to separate females from other males, or sequestering females from her social group, both functioning to prevent extra-pair copulations. Although findings are consistent with sexual conflict, specific tests of its relevance to sexual conflict are needed. For example, indirect benefits of having sexually coercive sons still need to be ruled out to qualify as a form of sexual conflict.

Sexual Conflict After Conception

Sexual conflict after mating occurs when there are conflicts in parental care of offspring because greater parental care can be costly by decreasing opportunities for additional mateships. Generally, one sex would benefit if the other sex invested more in their offspring. In nonhumans, this has been studied in the context of mate desertion and amount of offspring care. These ideas are now being applied to humans. For example, kin detection may impact parental investment (Platek and Ryan Porter 2012), and some evidence found that mothers and their family members typically suggest babies resemble fathers, possible to increase paternal care (Daly and Wilson 1982). Sexual conflict after conception also has implications on mate expulsion. Relationship dissolution may occur in response to costly actions from one's partner, such as infidelity, lack of investment, or

reduced sexual interest (Wade 2012). The operational sex ratio may impact sexual conflict where, for example, in female-biased sex ratios, men may be less inclined to invest in their partner and offspring. Buss also proposed how sexual regret could be a form of sexual conflict, presumably because its effect on increasing choosiness becomes costly to her pursuer.

Limitations to Sexual Conflict Research

There are several issues that limit research in sexual conflict (see Arnqvist and Rowe 2013), which includes isolating the effect of traits on fitness, and correlating the evolution of conflicting traits in males and females. Even if such correlations are found, there may be other explanations for such a relationship. Also problematic is that some traits are difficult to measure, analyses are based on the current function of a trait, and their effects are also difficult to measure because counterstrategies may mask preceding sources of conflict. There is also difficulty in ruling out indirect benefits, as was the case of females who are sexually coerced having sexually coercive sons, and in determining whether harm is a byproduct of a trait (i.e., *collateral harm*, neither sex benefits). Limitations to studying sexual conflict are even greater among humans since fitness costs and benefits are difficult to measure and experimentation is not possible. Attention to mathematical models, and triangulating results from multiple empirical methodologies, can help overcome such issues.

Conclusions

Sexual conflict may prove to be powerful theoretical model to explain the etiology of various human sex differences. Though much of the theoretical and empirical work has been conducted with non-humans, scholars are now pursuing its application to human psychology. Examples of human sexual conflict includes sexual deception and sexual exploitation (conflict before mating), cuckoldry risk (conflict during mating), and child

support (conflict after mating). However, only a few studies have directly tested hypotheses derived from intralocus sexual conflict in humans, and to the author's knowledge, no direct tests of human interlocus sexual conflict have been conducted. The application of sexual conflict to human psychology would benefit from careful empirical tests of specific hypotheses derived from this middle level theory.

Definition

Sexual disgust is an emotion that functions to motivate individuals to avoid the pursuit or acceptance of fitness-compromising sexual behaviors.

Introduction

Sexual reproduction likely evolved because, relative to asexual reproduction, it produces offspring that are better equipped for battle in arms races

against pathogens (Ridley 1993). In light of its evolutionary history, the fact that sexual intercourse can result in genital warts, herpes, chlamydia, and HIV (among other infectious diseases) can seem like a humorous counterattack from pathogens. Of course, the pathogens transmitted sexually are not necessarily the same ones that would benefit from a pool of genetically homogeneous hosts; specific viruses and bacteria (along with other critters) have evolved to occupy a niche in the ecological space created by reliable genital-to-genital contact between conspecifics. These sexually transmitted pathogens – along with other consequences of sexual contact – have favored host counter-adaptations that function to reduce the fitness-impairing consequences of sex. Some of these adaptations are psychological, and some of these psychological adaptations shape sociosexual orientation, preferences for sexual variety, preferences for specific traits in partners, and emotional sensations, including sexual disgust.

Sex and Pathogens

Whereas mammalian predators have evolved to use stealth attacks and brute strength to make contact with (and, then, consume) their prey, pathogens have evolved to invisibly hitchhike into their hosts (including us) via our food, our water, our air, and our social partners (Tybur et al. 2013). Given that all humans must eat, breath, drink, and share contact with conspecifics, the psychological adaptations regulating these behaviors are likely designed to trade off benefits of contact against (pathogen) costs of contact (Tybur and Lieberman 2016). The psychological adaptations regulating mate choice should similarly weigh the benefits of contact (typically, a chance at conception) against the pathogen costs of sex.

The genitals are warm and moist, and one of their functions (transmitting or receiving gametes) requires sustained contact with another individual's genitals. They are, then, an ideal location for pathogens to reside, comfortably housed within one host and ready to be transmitted to another. Further, sexual behavior also involves extensive

nongenital contact, with skin touching skin and, in many cases, mouths touching skin, mouths, and genitals. Although pathogens transmitted via air droplets (e.g., tuberculosis) and skin contact (e.g., ringworm) are not typically referred to as “sexually transmitted” infections, they are more readily transmitted during sexual interactions than during other social interactions that require less contact.

The pathogen consequences of physical contact have likely shaped the evolution of human sexuality; indeed, researchers have proposed that the pathogen costs of multiple sexual partners can favor the evolution of monogamy (Loehle 1995) and may have done so especially in humans (Mackey and Imerman 2000). Mathematical simulations suggest that the pathogen costs of sex can affect sexual strategies, though they do not necessarily uniformly favor monogamy; instead, they can increase variability in monogamy versus promiscuity (Boots and Knell 2002; Kokko et al. 2002b), or they can favor monogamy versus promiscuity depending on pathogen virulence (McLeod and Day 2014). In sum, simulation studies suggest that pathogen costs of sex can influence sexual strategies and they detail the nature of these consequences under different transmission conditions.

Of course, while we can be confident that sexually transmitted pathogens were present in the human ancestral past, their virulence, frequency, and fitness consequences (and, hence, their ultimate impact on human sexual psychology) are difficult to estimate. Research programs dedicated to understanding how pathogens have shaped human sexual psychology have thus more frequently generated and tested hypotheses of how mate preferences vary across individuals and contexts.

Pathogen Avoidance and Sexual Strategies

Having a large number of sexual partners can provide several benefits, including protection, increased offspring number, and increased offspring diversity (Buss and Schmitt 1993). Of course, people do not seek to maximize their number of sexual partners, since the costs of having more partners often exceed these benefits (Gangestad and Simpson 2000). One of these

costs is pathogenic – each successive sexual partner risks exposing an individual to a new collection of pathogens. Individuals might weigh these benefits and the pathogen costs of sex differently, with those who are more invested in avoiding pathogens favoring a less pathogen-risky sexual strategy (i.e., fewer partners). Some research is consistent with this idea. Sociosexual orientation – the degree to which an individual is open to sex outside of a long-term relationship – is negatively related to the degree to which an individual is motivated to avoid pathogens, as assessed by measures of (pathogen) disgust sensitivity and contamination sensitivity (Duncan et al. 2009; Murray et al. 2013; Tybur et al. 2015). Such patterns are mirrored at the national level, with individuals in higher parasite stress countries having more restricted (monogamous) sociosexual orientations (Schaller and Murray 2008).

Reducing sexual partner number is not the only way to mitigate the pathogen costs of reproduction; one can also limit sexual contact to the minimum required for conception (i.e., penile-vaginal intercourse). Individuals more invested in avoiding pathogens appear to do so. Sensitivity to pathogen disgust and contamination sensitivity both relate to the degree to which individuals report being disgusted by a range of sexual acts, including anal sex, oral sex, multiple partners, and even watching erotic videos (Tybur et al. 2009, 2015). Again, cultural level findings mirror individual differences findings, with individuals in higher parasite stress cultures engaging in less romantic kissing (Murray et al. 2017).

Pathogen Avoidance and Mate Preferences

In addition to influencing sexual openness, pathogen-neutralizing aspects of our mating psychology might also influence the types of sexual partners an individual prefers. Potential partners vary in both their current infectiousness (sexually transmitted or otherwise) and their likelihood of being infectious in the future (see Tybur and Gangestad 2011, for an overview). To an individual selecting a mate, the former has immediate infection consequences, and the latter can have future infection or investment (parental or otherwise) consequences, should a long-term,

interdependent relationship be established and maintained. If infection consequences of partner choice have shaped mate selection psychology, we might observe that individuals who invest effort in avoiding infections prefer individuals with a lower likelihood of infection. A body of evidence suggests that this is indeed the case. Multiple studies have found that women who are more disgusted by cues to pathogens have stronger preferences for masculine faces, voices, and body shapes in men (DeBruine et al. 2010b; Jones et al. 2013), which putatively signals health (Folstad and Karter 1992). Individual differences studies on pathogen disgust and masculinity preferences are complemented by evidence suggesting that, in nations with greater health problems, women prefer greater masculinity in male faces (DeBruine et al. 2010a). Another study finds that individuals exposed to cues to pathogens report greater preferences for dimorphism and symmetry in opposite-sex faces (Little et al. 2011), and another finds that childhood illness predicts preferences for dimorphism in opposite-sex, but not same-sex, faces (de Barra et al. 2013). Still another finds that men higher in pathogen disgust prefer women with lower waist-to-hip ratios (Lee et al. 2015), which are associated with long-term health and fertility (Jasienska et al. 2004; Singh 1993). Finally, evidence suggests that individuals higher in pathogen disgust sensitivity are especially unattracted to individuals low in physical attractiveness (Park et al. 2012), which can be viewed an aggregate perception of a bundle of reproductively relevant qualities (Miller and Todd 1998), one of which might connote current infectiousness or parasite resistance (Henderson and Anglin 2003; Thornhill and Gangestad 1993).

Although this literature indicates that there is a relationship between mate preferences are influenced and pathogen-avoidance motives, the exact nature of that relationship – and its implications for understanding how mating preferences function to neutralize the infection consequences of sex – remains opaque. The relationship between human sexual dimorphism and current or future infectiousness is unclear (Kokko et al. 2002a; see also Scott et al. 2012), as is the

relationship between attractiveness and global health (Weeden and Sabini 2005). Further, findings from one study suggest that pathogen disgust sensitivity relates to masculinity preferences only among young adults (Lee and Zietsch 2015). And other findings suggest that masculinity preferences in health-challenged societies reflect preferences for intrasexual competitive ability (and, perhaps, protection) rather than immunocompetence (Brooks et al. 2011). In sum, then, some evidence casts doubt on the hypothesis that preferences for sexual dimorphism or attractiveness function to select mates who are able to resist infection. Nevertheless, pathogen-avoidance motives could relate to preferences for certain traits (including sexual dimorphism) even if those traits connote benefits apart from immunocompetence. Any physical contact with a conspecific – and, especially, sexual contact – presents an infection risk. Individuals more avoidant of pathogens might show stronger preferences for dimorphism, attractiveness, or symmetry if they require higher-quality mates (e.g., in terms of fertility or intrasexual competitive ability) to risk the infection chance of any contact. Further research is needed to test this possibility and to clarify apparent inconsistencies in the literature.

Sexual Disgust: More Than Just Pathogens

When asked to describe things that are “disgusting,” many individuals nominate sexual behaviors (Tybur et al. 2009). Given the fact that disgust motivates the avoidance of pathogens (Tybur and Lieberman 2016), disgust toward sex can, at first blush, appear to solely function to motivate the avoidance of the pathogen consequences of sex. A closer look at sexual disgust suggests something different. Consider incest, the most universal of sexual disgust elicitors. Although sex with a sibling exposes an individual to comparable infection risk as sex with an unrelated individual of a similar age and attractiveness, the former elicits disgust, and the latter can elicit arousal (or, perhaps, less disgust). The consequences of incest that lead to disgust are thus unlikely to be pathogenic; instead, they likely reflect the poor genetic compatibility of close relatives and, ultimately, the opportunity costs that come along with

investing finite time and energy into a poor reproductive partner (Tybur et al. 2013). Other instances of sexual disgust might similarly function to attenuate broader costs than those imposed by pathogens. A physically unattractive individual might elicit disgust when considered as a sexual partner, but might be a perfectly acceptable partner for another task that requires close physical contact and, hence, risks pathogen transmission. Again, disgust toward sex with this partner would primarily be reflecting motivations to avoid the opportunity costs of reproducing with an individual of limited sexual value rather than avoiding contact with an infectious individual.

Sex differences in sexual disgust are consistent with this perspective. In the development of the Three Domain Disgust Scale, Tybur et al. (2009) report that women score 1.51 standard deviations higher on a sexual disgust instrument, but they score only 0.15 standard deviations higher on a pathogen disgust instrument. Whereas the sexes pay similar infection costs in the event of contact with pathogens (cf. Fleischman 2014), they suffer vastly different opportunity costs from sex. Whereas men can be saddled with reputation costs and social pressure to invest in a sexual partner or offspring, women can lose the opportunity to reproduce for the period of gestation and beyond and pay high energetic costs in the event of pregnancy (Buss and Schmitt 1993).

The Function of the Qualia

In comparison to the sensation of pathogen disgust, which seems tailored to motivating the avoidance of physical contact with pathogens (Oaten et al. 2009; Tybur et al. 2013), the function of the sensation of sexual disgust is less clear. On the one hand, it could function to motivate physical avoidance of individuals perceived as having low sexual value (e.g., relatives, individuals of poor genetic quality). On the other hand, other emotions more efficiently motivate avoidance (i.e., fear) or dissuade others from pursuing sexual contact (i.e., anger). Of course, flight and/or aggression in response to sexual advances is also costly, and sexual disgust might motivate sufficient avoidance to communicate a lack of sexual receptivity to a courting individual. That said, if

sexual disgust functions primarily to communicate a lack of interest, then the sensation of disgust might motivate verbal and nonverbal behaviors, including facial and vocal expressions of disgust, that signal a lack of interest to a courting individual. More empirical work is necessary to elucidate the manner in which sexual disgust might mitigate the costs of sex.

Conclusion

Mathematical simulations and behavioral science data support the theory-based arguments that some aspects of human sexual psychology function to neutralize pathogens. The precise nature of these psychological mechanisms remains unclear, though, as is their contribution to acquiring mates who are currently noninfectious or who are likely to be noninfectious in the future. Similarly, although humans clearly experience sexual disgust, the function of the qualia remains unclear, and further research is needed to adjudicate between competing hypotheses.

Synonyms

[First coitus](#); [First intercourse experience](#); [First sexual behavior](#); [Sexual initiation](#)

Definition

Generally, the time one experiences heterosexual sexual intercourse (e.g., vaginal-penile) for the

first time; increasingly, sexual debut also includes sexual experiences not involving penile/vaginal intercourse such as anal intercourse.

Introduction

Evolutionary theory posits that an integral developmental process in adolescence is the attainment of reproductive status. This occurs when an adolescent develops “physical and social competencies needed to gain access to a new and highly contested biological resource: sex and, ultimately, reproduction” (Ellis et al. 2012, p. 615). Through developing these competencies, adolescents and young adults may become sexually promiscuous and competitive (Weisfeld and Coleman 2005) leading them to engage in sexual behavior or experiencing their sexual debut. Considering the importance of this evolutionary milestone, it is essential that a holistic understanding of the precursors and implications of sexual debut is constructed. Research on sexual debut, and therefore the organization of this entry, has mainly focused on: (1) rates and timing of sexual behavior; (2) risks associated with early sexual debut; (3) protective factors against early sexual debut; (4) outcomes of early sexual debut; and (5) additional considerations in understanding sexual debut.

Rates and Timing

The average age of sexual debut for girls and boys in the United States is 17 (Carlson et al. 2014). When considering timing of sexual debut beyond the age of the adolescent in years, developmentally appropriate age cutoffs are often selected. Based on current norms in the United States, three categorizations are utilized to show early (before age 15), middle (or normative, between ages 15 and 19), and late sexual debut (after age 19; Harden 2014). Other studies contextualize the timings a bit differently considering sexual debut that occurs before the age of 16 early, and normative between the ages 16 and 19 (Spriggs and Halpern 2008). These differences can be explained through understanding the different

definitions of sexual debut. For example, in one study, earlier ages of sexual debut often include both sexual intercourse and other sexual behavior. On the other hand, when the later ages are used, the authors of the studies are usually considering only intercourse, or coitus. Taking into account the differing psychological and social outcomes of having sexual experiences at different development stages can help determine the long-term implications that timing of sexual debut has on personal well-being and romantic relationships in later adolescence. Effects of early sexual debut, such as drug and alcohol use, mental health problems, or divorce, extend into adulthood as well. We discuss the findings in these areas in section four.

There are a host of demographic characteristics that affect the age at sexual debut. For instance, boys (as compared to girls; Jordahl and Lohman 2009) and sexual minorities are at higher risk of having earlier ages of sexual debut (Brown et al. 2015). Further, African-American adolescents are more likely than their Hispanic counterparts to have their sexual debut before the age of 14. Hispanic adolescents, in turn, are more likely than White adolescents to have their first sexual experience prior to age 14. In addition, Asian males experience later sexual debut than their Hispanic, White, or African-American counterparts (Cavazos-Rehg et al. 2009). Pubertal timing has also been shown to influence the age of sexual debut in that individuals who reach puberty earlier than their peers are more likely to have early sexual debut (De Genna et al. 2011).

Given the increase in attention paid to sexual relationships that occur outside of a romantic relationship (e.g., hooking up), it is important to consider not only when adolescents are choosing to have sex but also with whom (Boislard et al. 2016). For example, although the majority of teenagers were “going steady” with the partner with whom they had their first sexual experience, 13% of girls and 27.3% of boys had their first sexual encounters with a friend, not a romantic partner. These rates vary greatly by race/ethnicity. While 20.7% of White teen males had their first sexual encounter with someone with whom they were “just friends,” 40.5% of non-Hispanic Black teen males experienced their first sexual encounter

with a friend (Abma and Martinez 2017). Thus, an evolving research area calls for investigation into the context of adolescents’ first sexual experience rather than simply the age alone. That is, the relationship of the adolescent to their partner may be important given almost a quarter of adolescents have their sexual debut with a friend rather than someone with whom they are in a romantic relationship (Abma and Martinez 2017). While most people experience their sexual debut in adolescence, the aforementioned contextual factors vary greatly among individuals. It is therefore important to note these as well as the following risk and protective factors in developing programs, policies, and research to encourage optimal development.

Risks Factors

Numerous characteristics are shown to influence or promote early sexual debut. Many are typically defined as characteristics of adverse environments that lead the adolescent to adopt an accelerated reproductive strategy including initiating sexual behavior at an earlier age. For example, adolescents raised in low family income households and those whose fathers are absent (specifically in boys) tend to have earlier ages of sexual debut (Xu et al. 2018). Moreover, research has shown specific family structures such as parental cohabitation, single-mother headed households, and stepfamilies are associated with adolescent engagement in early sexual debut (McCutcheon et al. 2018). These associations clearly demonstrate the importance of the family context on sexual debut.

Further, delinquent adolescents have a higher likelihood of experiencing early sexual debut than their nondelinquent peers (Jordahl and Lohman 2009). This may be due to the strong influence peers have on adolescent sexual behavior (Savolainen et al. 2015) and the link between early sexual debut and delinquency. Further, drug use and depression are both linked to early sexual debut (Koleva and Stuart 2014). Taken together, it is important to consider many of these risk factors concurrently when working

with adolescents in a clinical, research, or educational setting.

Protective Factors

A positive framework surrounding sexuality in adolescence is only recently gaining traction in this field of research. Thus, information on protective factors is dwarfed by the details discussed pertaining to the risk factors. Despite this, there *are* protective factors that help to delay early engagement in sexual experiences. For instance, rather than family composition, recent research has shown that the family context has a protective influence on sexuality (Brown and Shillington 2017). That is, while adolescents whose parents are divorced are more likely to experience early sexual debut, a positive mother-child relationship can help overcome this risk factor (Sieving et al. 2000). Further, there is evidence showing that high maternal education (Jordahl and Lohman 2009), parental support (Moore and Chase-Lansdale 2001), and, in boys, early parental monitoring (Lohman and Billings 2008) can all serve as protective factors against early sexual debut.

Beyond the immediate family context, school environment and peers can also serve as protective factors. As stated above, peers have a strong influence on adolescent sexual behavior (Sieving et al. 2006). Specifically, when peers delay sex, adolescents are also more likely to engage in this behavior at later ages (Ajilore 2015). Moreover, performance in school is also associated with sexual behavior in adolescence such that higher grades are indicative of fewer sexual partners (Paat and Markham 2016). Given the outcomes of early sexual behavior, discussed below, it is imperative that both risk and protective factors are incorporated in efforts to create policies and interventions that delay sexual behavior.

Outcomes of Early Sexual Debut

Rates of early sexual initiation are associated with a host of psychological and behavioral outcomes during adolescence as well as over the lifespan.

For example, individuals who have sex at earlier ages are more likely to be diagnosed with lifetime sexually transmitted infections (STIs) in adulthood. Those who have sexual debut early are also more likely to experience teenage pregnancy (Finer and Philbin 2013). However, this is typically also associated with a lack of use on contraception in younger ages. In addition, teens who experience their first sexual encounter at earlier ages will delay the use of contraception (Finer and Philbin 2013), not use condoms, and have more sexual partners (Lowry et al. 2017) leaving them at risk for STIs and unintended pregnancies. These teens are also less likely to complete high school (Bengesai et al. 2018; Spriggs and Halpern 2008).

Also considered a risk factor (discussed above), delinquency has been shown to be an effect of early sexual debut in that adolescents who have earlier sexual debut are more likely to engage in delinquent behavior than their peers who have late or on time sexual debut (Armour and Haynie 2007). Research needs to address the co-occurrence of these behaviors prospectively over time.

Early sexual debut has also been associated with mental health symptoms in adolescence and adulthood. Specifically, Vasilenko et al. have found that having an early sexual debut predicts depression in adulthood (Vasilenko et al. 2016). However, others have shown that early sexual debut was associated with depression in adolescence, but not in adulthood and only in adolescent girls under the age of 16 (Spriggs and Halpern 2008). This association does not appear in boys or girls who have on time initiation or had not yet had their sexual debut. Finally, this association dissipated over time indicating that the long-term effects are less or nonexistent.

Further Considerations

The literature on sexual debut mainly focuses on sexual behavior in adolescence in opposite sex encounters with few studies asking for specific information on same sex sexual experiences. Recent estimates show that 20% of individuals

age 18–34 identify as LGBTQ (lesbian, gay, bisexual, transgender, or queer) compared to 12% of adults age 35–51 and 7% of adults age 52–71 (glaad 2017). Therefore, there is room for growth in this area of research and practice. One way to change the heteronormative research surrounding sexual debut may be to ask about specific sexual behavior at different ages. Indeed, while the majority of individuals report vaginal intercourse at their sexual debut, other behaviors such as oral or anal sex should also be considered.

Further, there is a large body of literature looking at sexual debut among adolescence; however, there is a dearth of research focusing on same-sex sexual debut. While most people can agree on the definition of “coitus,” an agreed upon definition of sex that transcends orientations is nonexistent (Carpenter 2001). This lack of an overarching definition of sexual debut that encompasses all sexual orientations complicates our understanding of the influences and outcomes of sexual debut among sexually minoritized individuals. Indeed, the experiences of individuals whose first sexual experience is with a person of the same gender have been heretofore often excluded (Kreager et al. 2016). It is important that the term “sexual debut” is operationally defined clearly in studies so practitioners, researchers, and policy analysts can successfully contextualize the study findings so as to accurately apply them to specific populations.

Conclusion

Further clarification is warranted in our understanding of what exactly sexual debut means (e.g., how is it defined) and how it fits into the evolutionary understanding of human development. While there is a wide body of literature regarding the influences and outcomes of normative and nonnormative sexual debut, simply referring to sexual debut as “coitus” or initiating sexual behavior leaves inordinate ambiguity in our understanding of how this behavior affects adolescents. Acknowledging the variables associated with early sexual debut, clinicians should assess patients with early sexual debut for substance

use, sexual risk taking, depression, and STIs. Moreover, due to the simultaneous existence of many of these constructs, adolescents exhibiting any of these should be screened for these poor mental health symptoms, STIs, substance use, and other risk behaviors.

Given that many of the aforementioned outcomes are also risk factors of early sexual debut (i.e., delinquency), comprehensive sexual education should be developed to include information about sexual abuse – coercion – and delinquency – such as drug use – prevention (Lowry et al. 2017). Additionally, this education should be implemented early, giving adolescents accurate information regarding aspects of sexual behavior using age appropriate techniques. It is important to remember that sexual debut at younger ages is more likely to be coerced than when it occurs at later ages (Finer and Philbin 2013). Considering this association between coercion and early sexual debut, adolescents would benefit from learning about consent from their teachers and parents as early as kindergarten. Engaging adolescents in these discussions at younger ages, before sexual risk behaviors occur, may help to deter adolescents from experiencing early sexual debut and therefore mitigate the negative, long-term effects (United Nations 2009).

In sum, existing research on sexual debut focuses heavily on risks and outcomes of first coital experience. Future research should thus consider, not only additional behaviors beyond penile/vaginal intercourse, but also other sexual behaviors which, when excluded, further marginalize LGBT populations. Additionally, policy makers should focus efforts beyond simply delaying age of sexual debut. Rather, focus should be redirected educating adolescents and children about sexuality to allow them the autonomy to make healthy, smart decisions about sex (Carter 2012).

Synonyms

Gender differences (i.e., culture and sense of being male or female); **Sex Differences**

Definition

Structural and behavioral differences between the sexes that have biological origins.

Introduction

Dimorphism in human secondary sexual characteristics is similar to those of other primate species in which competition between males (intraspecific) is coalitional in nature. However, humans are unique in the complexity of social competition, necessitating sexually differentiated and sophisticated socio-competitive competencies that require elaboration within the particular social and cultural ecology. Preferences begin with prenatal organization by androgens, resulting in sexually segregated social groups in childhood, which promote the sex specific elaboration of socio-competitive competencies necessary for adult reproductive competition and parenting.

Evolution of Sexual Dimorphism

Darwin (1871) noted that selection can occur in response to ecological conditions (natural selection), as well as interactions within a species (social selection), of which mate competition is a component (sexual selection). Sexual selection describes competition between males (intrasexual) for access to costly female gametes and parental investment, as well as discriminatory female choice (intersexual). Male competition and female choice are the general pattern, but there are role reversals and other nuanced discussions beyond the scope here (e.g., Clutton-Brock 2007). Sexual selection has been utilized to describe sexual dimorphism in hundreds of species as well as humans (Geary 2010). Sexual selection is especially powerful in species with internal gestation resulting in larger, aggressive males, with weapons, armor, or costly honest displays of fitness.

In primates, the intensity of competition between males is associated with sexual body size and canine size dimorphism (Plavcan 2001). When one male can monopolize many females

and competition is decided through contests, such as Gorilla, males are nearly twice the size of females. Monogamy and coalitional competition are associated with reduced dimorphism (Plavcan et al. 1995), which appears to be the case for chimpanzees and humans. The hominin fossil record describes extreme dimorphism early, which is diminished in humans, though men have on average 61% more muscle mass and 75% more upper body strength (Lassek and Gaulin 2009), suggesting that humans exhibit characteristics of combat competition (Hill et al. 2017).

Human Reproductive Ecology and Adaptations

To understand how selective pressures differ between the sexes, it is important to understand a species' reproductive ecology. Humans are generalists regarding ecological adaptations having achieved some amount of ecological dominance (Alexander 1990). The most uniquely human adaptation is the neocortex resulting in sophisticated cognitive capacities that support competition with conspecifics (for review Flinn et al. 2005). Working memory and executive functioning create the ability to mentally simulate social scenarios allowing planning, foresight, and mental time travel. Theory of mind allows humans to understand others and enables empathy. Moral emotions connect individuals and promote group beneficence in decision-making (i.e., guilt, pride, and embarrassment). Consciousness and multiple order reasoning allow complex deception and deception detection mechanisms. The end result is a brain that is three times larger than earliest fossil hominin and consumes 20% of our resting metabolism and 40% in infants. As a result, human infants are born uniquely altricial requiring the longest development and the most intensive parental investment, including paternal investment, which is unique for primates in the context of multi-male groups and extremely rare in mammals generally. Humans exhibit adaptations that promote male-female pair-bonding in adulthood, such as concealed ovulation, nonreproductive sexual intercourse, female orgasm, and romantic

love (Flinn et al. 2005). The nested human family with its extensive network of kin and affines serves to provision and nurture the most socially competent and competitive primate in accruing and elaborating extreme socio-competitive competencies necessary for successful mating in groups comprised of other such individuals (Geary and Flinn 2001).

Developmental activities are thought to result in refinement of physical, cognitive, behavioral, and social competencies that enhance reproductive prospects in adulthood (Geary 2010). Sex differences in developmental activities are predicted to the degree that the sexes differ in patterns of intrasexual sexual competition, intersexual choice, and parental investment (Geary et al. 2003). In humans the specifics of adult social competition occur across cultures, but the subtleties are specific to the social and cultural ecology, to which the human child is adapted during its developmental period (Geary 2006). For humans, coalitional competition between groups is lethal in nature, placing a premium on group size and cohesion, facilitated by within-group cooperation. Competition between women tends to be about the resources needed to reproduce, and as direct physical aggression reduces a woman's reproductive potential, it tends to be of an interpersonal nature placing a premium on sophisticated social skills that are both prosocial and indirectly self-serving.

Development of Human Sex Differences

Sexual differentiation begins with sex chromosomes, with males getting a Y chromosome which contains the SRY gene and begins the production of androgens, the most important of which is testosterone. Testosterone has masculinizing effects during critical periods. Once organized prenatally, testosterone remains low until puberty at which time it again organizes the brain and body, promoting male-typical secondary sexual characteristics. After puberty testosterone increases acutely in response to particular reproduction-related stimuli, such as status challenges and sexual stimuli. The organizational-activational framework describes the majority of

phenotypic differences between the sexes, though some have been shown to be related directly to the sex chromosomes, through genetic or epigenetic effects (for review Arnold 2017).

The prenatal organizational effects of testosterone result in early differences between the sexes in preferred stimuli and activities. For example, before social and cultural influences, looking time preferences in newborns indicate that females prefer looking at a human face as opposed to males looking longer at a mechanical object (Connellan et al. 2000). By 3–4 months, using looking times, males appear to recognize spatially rotated objects (Quinn and Liben 2008). By 6–8 months, viewing images of actual children, boys preferred looking at a group, while girls preferred looking at an individual (Benenson et al. 2007). Preferential looking time at 12, 18, and 24 months show girls preferring to look at dolls and boys prefer to look at cars (Jadva et al. 2010). That the sex differences occur so early suggests they are not the product of socialization, but rather the origin of social preferences and the resultant sexually differentiated behaviors, even in cultures where gender behaviors are not encouraged (Nelson 2005).

Beyond stimuli, preferences for activities are affected by prenatal testosterone measured in amniotic fluid which is associated with the development of male-typical play in boys (Auyeung et al. 2009). Even females exposed to high levels of testosterone prenatally (i.e., congenital adrenal hyperplasia) show a preference for male-typical toys, rough-and-tumble play, and male playmates (for review Hines 2014). However, genetic males (XY) unable to utilize testosterone (i.e., complete androgen insensitivity syndrome) develop as normal well-adjusted women (Wisniewsky et al. 2000). Early exposure to androgens appears to set in motion the development of preferences for male-typical social activities.

Developmental Elaboration of Sexually Differentiated Socio-Competitive Competencies

While many of the competencies elaborated during human development are similar between

the sexes, social and competitive styles are the exception. Beginning in infancy, females are more attuned to subtle social cues, such as looking at faces and identifying adult emotions, showing greater self-regulation, and exhibiting fewer negative emotions (Benenson 2013), whereas boys are more object oriented. Not surprisingly, as soon as the sexes begin to socialize, interpersonal style and differences in preferred activity push them apart into self-segregated peer cultures (Maccoby 1990), which provide separate venues for skill rehearsal and elaboration.

For boys, in an extensive review of the literature, Rose and Rudolph (2006) found that boys tend to have larger playgroups with well-defined dominance hierarchies and engage in rough-and-tumble and competitive play. Without direction, boys appear to be inherently biased to form groups and compete at the group-level (i.e., between groups) (Geary et al. 2003). Indeed, humans are the only species that engages in group-level social play (Alexander 1989). In contrast to girls groups, in which conflict tends to increase over time, boys' groups show conflict early on, but once the hierarchy is formed, within-group conflict ceases and between-group conflict increases (Savin-williams 1979). Girls' relationships are generally characterized as more prosocial interactions, however boys tend to be more socially gregarious given the opportunity, seeking out unfamiliar same-sex peers (Benenson et al. 2012) and forming relationships more readily. Boys tend to have more integrated social networks as their friends tend to also be friends with one another. Once formed, relationships are more durable (Benenson and Alavi 2004), and males are more likely to resolve conflicts with peers when they arise (Benenson et al. 2014) and more likely to express affiliative or reconciliatory behaviors after competitive encounters (Benenson and Wrangham 2016). As males progress through adolescence, the coalitions show greater role differentiation, with explicit goals, and less conflict within group.

In contrast to boys, girls' pretend play often involves parenting, dolls, and activities involving less explicit winners and losers. Girls tend to interact with one or two other girls; their

interaction tends to be characterized by greater expression of emotion and connection-oriented goals, self-disclosure, sensitivity to distress in peers, and seeking and providing of support (Rose and Rudolph 2006). In middle childhood, girl's dyads become more intimate and exclusive, characterized by unconditional acceptance, bonding through reciprocal discussions, and sharing vulnerabilities. Girls tend to compete through indirect means, disguising true intent, and use of gossip and backbiting aimed at damaging reputation and social networks of other girls. As girl's progress through adolescence and skills in interpersonal intimacy and indirect competition are honed, relationships become more stable and mutually beneficial, facilitative alliances which enforce egalitarianism in resource distribution (Benenson 2013). As a woman's concurrent and future offspring are in jeopardy if she is injured, women avoid direct aggressive confrontation (Campbell 1999).

By puberty, sex differences in social styles are divergent enough that the process of *coming together* is somewhat problematic (Maccoby 1998) and requires another period of skill development, one unique to humans termed adolescence. The hallmark of which is the assimilation of adult-like sociosexual and economic behavior (Bogin 1992). Sex hormones shift focus to cross-sex relationships and provide the impetus for the development of new skills that promote collaboration and ultimately reproduction.

Conclusions

As with other species, humans are relatively monomorphic until puberty. At puberty men exhibit traits associated with combat competition occurring between coalitions of males, and females display traits of fertility. As human social and cultural ecology is increasingly complex, sex differences in the socio-competitive competencies necessary for adult reproduction, require calibration and elaboration throughout the long developmental period. Sex differences in children's self-

initiated play activities are proposed to result in recreation of the social dynamics associated with sex differences in mate competition and parenting, and in so doing allow the practice and refinement of successful strategies (Geary 2010). Boys play in larger groups, prefer rough-and-tumble play, form dominance hierarchies, and practice competition between coalitions. Girls engage in play parenting and intensive dyadic social relationships, developing sophisticated linguistic and interactional skills that in adulthood allow indirect competition and reciprocal relationships with nonkin.

Sexual Dimorphism and Sex-Biased Gene Expression

Elina Immonen

Department of Ecology and Genetics, Uppsala University, Uppsala, Sweden

Synonyms

Sex-biased transcription; Sexually dimorphic gene expression

Definition

How evolution of sex differences in secondary sexual characteristics is mediated by evolution of sex differences in the relative expression of genes present in both sexes.

Introduction

In many species of animals and plants females and males differ dramatically in appearance, behavior, and physiology, referred to as sexual dimorphism. Such differences have evolved due to natural and/or sexual selection acting differently on the sexes. Sex-specific natural selection acts on traits that improve general reproductive success or survival in the given sex, while sexual selection

favors traits that improve mating or fertilization success, operating through competition among the individuals of the same sex or through mate choice. Such traits include, for example, sexual ornaments, weapons, and territorial behaviors that secure access to mates.

In most species with separate sexes females and males are genetically identical apart from the genes in the sex chromosome unique to only one of the sexes (such as Y of human males). In many others the sexes share all of the genes. How, then, do the vast phenotypic differences arise? The answer lies in how the shared genes are expressed in each sex. Studies from fruit flies (Zhang et al. 2007), mammals, birds (Ellegren and Parsch 2007), and plants (Zemp et al. 2016) to brown alga (Lipinska et al. 2015) show that a high proportion of the genome is differentially expressed in females and males. Genes that show higher expression in one sex relative to the other are referred to as sex-biased genes, detected using microarray and RNA sequencing technologies.

Transcriptional and Phenotypic Sexual Dimorphism Are Correlated

Sex-biased expression is a dynamic phenomenon, and the number of sex-biased genes as well as the degree of expression differences between the sexes depends on the tissue in question, the life stage (Perry et al. 2014), and the reproductive state of individuals (Immonen et al. 2017). Although the patterns can be variable, there is generally a strong correlation between gene expression dimorphism and sex differentiation of tissues, indicative of the importance of sex-biased expression in the development of sex-specific phenotypes (e.g., Mank et al. 2008; Perry et al. 2014; Immonen et al. 2017). A study on the male-polymorphic wild turkey also shows that the magnitude of sex-biased expression correlates with the degree of masculinization in plumage and behaviors of males (Pointer et al. 2013). Although not causative, this work provides important evidence of the relationship between phenotypic and transcriptomic sexual dimorphism.

Sex-Biased Expression Evolves to Resolve Sexual Conflict

Many researchers are interested in sex-biased genes because they are expected to evolve under sex-specific selection to allow females and males to optimize their reproduction differently, and thus to evolve sexual dimorphism. By doing so, sex-biased expression should resolve the so-called intralocus sexual conflict that arises when the sexes face contradictory selection pressures for the expression of shared genes (Ellegren and Parsch 2007). Intralocus sexual conflict can be measured as the genetic correlation between the sexes under sexually antagonistic selection. Compatible with the prediction, sex-biased loci tend to have a lower intersexual genetic correlation than loci with similar expression between the sexes (Mank 2017). It is unclear, however, whether the breakdown of intersexual correlation is the *result* of evolution of sex-bias, or if sex-biased genes have initially a lower intersexual correlation (Mank 2017). Other evidence comes from studies of genomic locations of sex-biased genes. Due to their unique inheritance pattern, sex chromosomes are predicted to be hot spots for loci with sexually antagonistic effects, resolved through evolution of sex-specific transcriptional regulation. If the process is cumulative, one can also expect the older sex chromosomes, or regions, to show a greater degree of sex-biased expression. Consistent with these, there is excess of sex-biased genes in the sex chromosomes of birds, *Drosophila*, mammals, aphids, and flour beetles (Wright et al. 2015), and in birds older regions of sex chromosomes show a greater magnitude of sex-bias compared to younger regions (Wright et al. 2015).

Sex-biased genes evolve rapidly both at the sequence and expression levels (Ellegren and Parsch 2007). Males often experience a higher intensity of sexual selection with a rapid evolution of male traits, and in many taxa (including *Drosophila*, mammals, *Caenorhabditis elegans*, and birds) genes with a higher expression in males (i.e., male-biased genes) follow the same pattern of fast divergence (Mank 2017). However, this is not the case in all taxa (e.g., Lipinska et al. 2015),

and it is also possible that in many cases faster evolution of male-biased genes may result from relaxed selection and drift rather than adaptive evolution (Mank 2017). Also, at any given life stage the direction of sex-bias may not necessarily indicate in which sex their function is most important, and thus when in the reproductive cycle and in which sex the selection is strongest (Immonen et al. 2017; Mank 2017). Nevertheless, sex-biased expression is a good molecular predictor of past or ongoing selection that operates differently on the sexes.

Sex Steroids Regulate Sex-Biased Expression

How sexual dimorphism develops over ontogeny is under endocrine control. Although studies of this are still scarce, sex steroids, such as testosterone and estrogen of vertebrates, should be especially important in modulating sex-biased expression and thus in alleviating intralocus sexual conflict. A work on the sexually size dimorphic brown anole lizard shows how intersexual genetic correlation for body size decreases during development, mirrored by increased sex-biased expression for genes involved in growth and metabolism. Testosterone is likely involved in this: treatment of juvenile females with testosterone causes a male-like pattern of gene expression, growth, energetics, and ornamentation (Cox et al. 2017). At the molecular level, conjectures about the mechanisms that allow expression to be decoupled in the sexes largely remain to be discovered.

Conclusion

Studying how genes are regulated in each sex is not only important for our fundamental understanding of biological differences between the sexes and how many dazzling ornaments and extravagant behaviors have evolved, but also vital for medicine where genetic differences between men and women can have clinical consequences. Overall there is good circumstantial support for the prediction that sex-biased expression is required for the evolution of sexual

dimorphism and alleviation of genetic conflict between the sexes, but several outstanding questions remain regarding the mechanisms and how selection operates on sex-biased genes. No doubt this vibrant field will continue to offer many important insights that increase our knowledge and awareness of exactly how different females and males are at the molecular level.

Sexual Fantasies

Catherine Salmon
University of Redlands, Redlands, CA, USA

Definition

Mental images, thoughts, or imagined sexual experiences that can entertain, preoccupy, and promote sexual arousal

Introduction

Sexual fantasies are perhaps the most common human sexual experience. Unlike many sexual activities, they are private and thus unconstrained by reality in terms of partner choice or the behaviors engaged in. As such, they are interesting because they can provide insight into the psychological mechanisms underpinning human sexual desires as well as resulting behaviors. The majority of people engage in sexual fantasy and, on average, men do so more frequently than women.

How Are They Studied?

Typically, the frequency and content of sexual fantasies are studied cross-culturally via questionnaires. Such measures may assess fantasies in terms of endorsing items on a sexual fantasy scale, asking participants to complete sentences in sexual scenarios, as well as describing their own fantasies with open-ended questions. They can also be studied by examining commercial erotic fantasy in the form of pornography or romance/erotic literature. These commercial products are unobtrusive measures of sexual fantasy. The results of surveys and unobtrusive measures are more often in agreement than not.

Common Fantasies

Some of the most common fantasies, as assessed by survey, reflect actual behavior, including touching/kissing and doing so while naked, watching a partner undress, oral sex, masturbating your partner, and intercourse in unusual positions.

When we examine fantasies as depicted in online pornography, for example, Pornhub reports that the top search terms in 2016 included lesbian, stepmom, MILF, teen, and stepsister, reflecting the “partner” being fantasized about (most frequently by men, the majority consumers on Pornhub). The most frequently searched for activities included massage, anal, threesome, lesbians scissoring, and creampie. Interestingly, some

categories viewed more often by women include gang bang, rough sex, and bondage.

Perhaps unsurprisingly, the sexual fantasies of lesbians and gay men tend to be similar to those of heterosexual members of their gender, aside from the sex of their imagined partner.

Rape Fantasies

Many women and some men report that the content of their sexual fantasies includes imagined scenes of rape or sexual coercion. In Bivona and Critelli’s (2009) study, 62% of female undergraduates had experienced rape fantasies, some as often as once a week. While a small percentage found them completely aversive, the rest of the sample was split between those who found such fantasies erotically exciting and those that experienced them with a mix of aversion and arousal. The researchers interpreted this as attempts to deal with fears of rape but they also reported that most participants rated these fantasies as positive. The fact that these fantasies reportedly involved perpetrators who were known to the women experiencing them, good-looking, desirable men who in the fantasies exhibited an irresistible attraction to the woman echoes the theme of rape in romance, that is, can be about the appeal of the heroine as well as the sexual appeal of dominant men (Hazen 1983).

Do such fantasies indicate anything about the women who experience them? Not in the way that many people might assume. Strassberg and Lockerd reported in a (1998) study that women who engaged in forceful sexual fantasies, rather than experiencing some sexual pathologies, were in fact better adjusted sexually in that they experienced less sexual guilt and experienced more sexual fantasies in general.

Theoretical Approaches and Sex Differences

While social scientists usually attribute sex differences in sexual fantasies to sex differences in life

experiences, and it may be the case that much intrasex variation in sexual fantasy is due to such environmental effects, from an adaptationist perspective, one would expect selection to have shaped sexually dimorphic mechanisms underlying human sexual desires and dispositions. This would be expected because throughout human evolutionary history, men and women encountered substantially different reproductive opportunities and constraints. The male problem of paternity uncertainty and differences in the minimum possible parental investment between mammalian males and females are just two features of human sexual reproduction that would produce sex differences in human sexual psychology. Behavioral differences between men and women in sexual behavior and mate preferences are well documented.

In addition, there are many empirical studies of the frequency and content of male and female sexual fantasies that have documented substantial sex differences (Ellis and Symons 1990; Leitenberg and Henning 1995). Men engage in fantasy more frequently than women during the day as well as during masturbation or sex with a partner. Studies over the past 20–30 years have reported not only sex differences in frequency but also in the content of these fantasies. Women's fantasies are less dominated by physical images and more commonly emphasize touching, feelings, their partner's response (being the focus of their partner's desire), their emotional states, the special nature of their partner, and are more personal, often being focused on someone they were or had been romantically involved with. Men's fantasies are more visual, especially with relation to the genitals, involve more partners and more variety, and are more impersonal. In other words, they are more about just sex than about sex with a specific individual, which should not be surprising considering the importance of variety and partner number to maximizing mammalian male reproductive success and the importance of female choice to mammalian female reproductive success (Salmon and Symons 2003).

Conclusions

Sexual fantasies, like sexual behavior, reflect sexual psychologies shaped by the problems ancestral men and women faced in the mating domain. In some ways, sexual fantasies reveal more about the design of our sexual psychological mechanisms than behavior itself does, as fantasies or desires are unconstrained by reality in terms of ideal partners and behaviors. In particular, if real-life heterosexual encounters are constrained by inevitable compromises between men and women and thus blur their differences, the study of sexual fantasies can facilitate a more clear understanding of some of these sex differences in sexual psychology.

Sexual Fantasy

Christian Joyal
University of Quebec, Trois-Rivieres, QC,
Canada

Synonyms

Mental imaging; Sexual arousal; Sexual daydreaming; Sexual reverie

Definition

Sexual fantasy refers to any mental imagery that is sexually arousing or erotic to the individual (Leitenberg and Henning 1995).

Introduction

Contrarily to traditional psychanalytic points of view, sexual fantasies are associated with a more active and satisfying sexuality. In this entry, it will be suggested that sexual fantasies are generally adaptive from an evolutionary perspective because they serve to enhance sexual arousal which, in turn, increases the likelihood of intercourse, orgasm, and, eventually, reproduction. However, the number of studies devoted to sexual fantasies of adults from the general population is still surprisingly low.

Sexual Fantasies Among the General Population

Approximately 90% of the general adult population acknowledge having sexual fantasies. This type of mental imaging is important for sexuality as it is closely associated with sexual arousal, better sexual satisfaction, and higher odds of interpersonal sexual relation (Leitenberg and Henning 1995). In opposition, paucity or the absence of

sexual fantasy is associated with elevated age, low steroid hormone production, and asexuality. Therefore, and contrarily to classic Freudian assumptions, sexual fantasies do not reflect an absence of sexual activity or a compensatory mechanism for sexual dissatisfaction and deprivation, on the contrary. Higher diversity of sexual fantasies is also reported by persons with higher rates of sexual arousal (Joyal et al. 2015). Thus, sexual fantasies could be considered as adaptive from an evolutionary point of view, elevating the odds and frequency of interpersonal sexual relations.

Traditionally, emphasis is put on gender differences in studies of sexual fantasies. Although both men and women have intimate fantasies (e.g., involving their current partners) in similar proportions, men, on average, fantasize more about impersonal relationships, visual descriptions, and dominating behaviors, whereas women fantasize more about romance (feeling, ambiance, and location) and submission, in more emotive and cognitive descriptions (Ellis and Symons 1990; Leitenberg and Henning 1995). It should be noted, however, that these differences are based on group average comparisons. A more nuanced picture emerges when different subgroups of men and women are defined according to their sexual fantasy patterns, i.e., as a function of the type, diversity, and intensity of their sexual fantasies. For instance, there are at least four subgroups of women with different sexual fantasy profiles among the general population, including two with sexual fantasies as intense and diverse (if not more) than those of men (Joyal 2015). Interestingly, women with both typical fantasies and fantasies of domination–submission report higher diversity and intensity of fantasies in general and sexual satisfaction in general (Joyal et al. 2015; Joyal and Carpentier 2017). These women have intimate and romantic fantasies, and they include their current partner in their fantasies, but they also report a diversity of domination–submission themes that are still considered as “anomalous” in current psychiatric diagnosis manuals (APA 2013; see ► “Paraphilia” entry).

Therefore, it seems that diversity, more than content of sexual fantasies, is a sign of a healthy sex life. Diversity of sexual fantasies is associated with higher libido and, maybe, better reproduction fitness by virtue of a higher frequency of coital relations. This hypothetical link between diversity of sexual fantasy and higher rates of intercourse deserves to be tested.

The difference between a sexual fantasy and a sexual wish should also be underscored. Although the majority of male sexual fantasies are wishes, this is not necessarily the case for female sexual fantasies, especially those with submission themes. Women with coercive submissive or forced sexual fantasies commonly specified they would never want to act them out (Joyal et al. 2015; Leitenberg and Henning 1995). These sexual fantasies are simply mental scenarios helping to increase sexual arousal, not the sign of a genuine interest in the behavior. Therefore, sexual fantasies should not be confounded with sexual interests, especially in women.

Sexual Fantasies Among Sexual Offenders

Sexual fantasies may be useful in risk assessment of sexual offenders because they commonly precede (and succeed) aggressions in line with the fantasy (e.g., Grundmann et al. 2016). However, content is less important than usually expected in the prediction of an acting out. First, many men from the general population have similar sexual fantasies with illegal content (e.g., coercion, rape, voyeurism; Joyal and Carpentier 2017). Second, contrarily to popular belief, sexual offenders generally have less numerous and less diverse sexual fantasies than men from the general population, on average. Mental imaging, daydreaming, and fantasies are associated with mentalization capacities (i.e., taking the perspective of others, evaluating future consequences of a behavior, reflecting before acting) and executive functions (i.e., behavioral inhibition, problem solving). Given that these cognitive aptitudes are severely impaired, on average, in sexual offenders, it is not surprising that most of them possess a poor

inner world with few sexual fantasies. These sexual fantasies, however, are much more intense and frequent, if not obsessional, than those of men from the general population. Thus, it is not solely the content of a sexual fantasy but also (and mostly) its recurrence, intensity, necessity, and the lack of overall diversity that seem crucial to evaluate risk of acting out.

Conclusion

It is clear today that sexual fantasies are usually healthy unless they are rigid, rather exclusive, recurrent, and intense. In these cases, poor mentalization and executive functioning might lead the person to act out his/her sexual fantasy even if it is illegal. For the vast majority of people, sexual fantasies are diverse, and they serve to enhance sexual arousal, odds of interpersonal sexual relation, and higher sexual satisfaction.

Sexual Harassment

E. Alexandria Cozanitis
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonyms

Impropriety; Offensive sexual advance; Sexual intimidation; Unwanted sexual advance

Definition

Any unwelcome sexual conduct.

Introduction

The definition of harassment may vary depending on its social or legal context, however the *Equal Employment Opportunity Commission* provides the widely accepted definition as “unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature...” (Equal Employment Opportunity Commission 1980). The women’s advocacy group *Arming Women against Rape and Endangerment* (AWARE.org) differentiates the methods of harassment into three categories: verbal, visual, and physical.

Types of Sexual Harassment

Verbal sexual harassment constitutes any comment or remark that is of a sexual nature, or any sexually obscene or insulting sounds. This also includes any unwelcome and offensive names or terms of endearment. Examples of verbal sexual harassment include, but are not limited to, cat calls, kissing sounds, howling, whistling, and smacking lips, unwanted sexual teasing, jokes, remarks, or questions and comments of a sexual nature (A.W.A.R.E.org).

Visual Sexual Harassment is an assault to the sense of vision in which someone exposes his or her genitals or repeatedly stares at another person’s body in a way that is offensive or uncomfortable for the person at whom is being stared. Being made to look at sexually explicit images or being shown obscene sexual gestures may constitute visual sexual harassment as well. Other examples of visual sexual harassment can include obscene or unwanted sexual looks or gestures, unwanted letters, emails, text messages, and lewd images (A.W.A.R.E.org).

Physical Sexual harassment is the act of being coerced into unwanted physical contact, such as being brushed against, hugged, kissed or touched in any way that is unwelcome and discomforting. It may also include being forced to touch someone. Some examples of physical sexual harassment include unwanted pressure for sexual favors, touching an employee’s clothing, hair, or body in an inappropriate and non-consensual manner, making sexual gestures with hands or through body movements, and any attempt toward sexual assault and/or rape (A.W.A.R.E.org).

Sexual Harassment in the Workplace

In the workplace, the term *quid pro quo* describes harassment as sexual bribery if a person is coerced to submit to, or engage in sexual activity for professional advancement and receives favorable outcomes from the interaction, as in a favorable review (e.g., positive evaluation, better grade, etc.), promotion, or bonus. Sexual negotiations offer the can provide evolutionary explanations

for quid pro quo harassment depending on the status of the harasser, for example age, marital status and perceived attractiveness. *Hostile work environment* is a form of sexual harassment that is created when the individual in power presents a threat as a method to coerce the victim, requiring them to participate in an unwanted sexual behavior or suffer academic, professional, financial, or other loss. Although there is a distinction between the two, each is considered nonconsensual and abuse of power. Ultimately both subtle and unsubtle types of sexual harassment create problems in the workplace, for the person being harassed (Crooks and Baur 2014).

Sexual harassment is a modern socially constructed concept, specifically related to unwanted or coerced sexual attention or interaction. Evolutionary and feminist psychologies debate the causes of sexual harassment due to social contact, sexual motivation, and power expression to explain the complexity of this evolved characteristic of sexual behavior (Studd 1996).

Evolutionary Psychological Perspective

From the evolutionary psychological perspective, sexual harassment is the result of “evolved mechanisms guiding male motivation to strive for sexual access to females, which in ancestral environments had direct positive payoffs for male reproductive success in competition with other males” (Studd 1996, p. 61). In other words, males sexually harass as a means of attempting to increase their reproductive opportunities. Evolutionary psychological research has found support for this theory – noting that females who possess traits that are indicative of fecundity and reproductive availability (e.g., single, young, physically attractive) are more likely to be sexually harassed (Buss 2016). Reports have also concluded that unmarried males – those who have not secured a long-term mate – are more likely to engage in sexual harassment (A.W.A.R.E.), and women react more negatively to sexual advances by an offender who is married (Buss 2008; Studd 1996). Women also perceive sexual harassment as significantly more disturbing when the harasser is of

lower occupational status (Buss 2016), indicating that advances from males with low mate value (e.g., low status career with fewer resources) are more unwelcome than advances from males with higher mate value.

Sexual motivation hypothesis is an evolutionary perspective suggesting that sexual energy and activity are motivating factors behind harassment, and that these mechanisms have different reproductive investments for each gender (Buss and Malamuth 1996). Men that harass women through staring and implied or actual physical contact may be expressing an evolved behavior to measure waist-to-hip ratio and other signs of youth and symmetry of possible mates (Geher 2014; Platek and Singh 2010). This is consistent with evolutionary theory that males seek fecund females as potential mates.

Each sex’s perception and interpretation of mating-related behaviors may also be different. Error management theory posits that cognitive differences between the sexes can play a role in dating and mating strategies where persistent men mistake harassing behavior as flirtation (Haselton and Buss 2000). Men and women share a misperception that there is no difference in the perception of feelings toward aggressive behavior between the sexes; however, in reality, research shows that men often overperceive sexual interest from females – which may cause the male to pursue the female even though she is not interested, which may lead to sexual harassment – while women tend to underperceive sexual interest from males – which may cause the female to interact with a male who is sexually interested in her, but she is unaware of it (Haselton and Buss 2000).

Cognitive processes of human ancestry are slow to change, but consequences of the behavior have been adapted to create the modern cultural views against sexual harassment. When individuals do not welcome the advances or attention, the act is then defined as harassment. While these actions may seem harmless, research has shown that women find sexual aggression to be more disturbing than men do (Crooks and Baur 2014; Studd 1996). Investigations of legal documents from sexual harassment cases support

this evolved mechanism of defense – the more blatant harassment led to more negative responses from the women who were harassed (Studd 1996, p. 63).

The social contact hypothesis predicts that men who have prolonged contact with women young enough and available to reproduce, motivates men to initiate sexual intentions, whether the behavior is welcome or not (Studd 1996). Women's presence in the once male-dominated work and educational environments has given rise for social contact to work. Opportunities are made available through social contact, which helps to explain the motivations of inappropriate sexual behavior in the workplace and in educational settings. When men and women share personal interests and functions such as school, work, or military service, they have accessibility to potential partners with common interests. Understandably, men and women who work together can and do develop genuine affection and attraction towards each other when they work, study, or serve together (Buss 2008). When one of the two do not consent, the dynamic of the interaction fits the legal definition of sexual harassment.

Feminist Psychological Perspective

The feminist perspective holds that power and male dominance are motivating factors behind sexual harassment, and are logical cornerstone concepts to the explanation in social psychology. In other words, the feminist view regards actions of harassment as expressions of power over women, rather than sexual in nature. This is often referred to as the power hypothesis (Studd 1996). "In general the feminist perspective on sexual harassment proposes that the exercise of power is the causal factor for the occurrence of unwanted sexual attention in the workplace" (Studd 1996, p. 56). As women strive to gain equality through professional success, 40–70% of American women have experienced sexual harassment in the workplace according to data analysis from the Equal Employment Opportunity Commission in 2009 (Crooks and Baur 2014).

Between 75% and 90% also report adverse psychological effect from this behavior and findings estimate that of those who have been sexually harassed only 5–15% will file an official complaint (Crooks and Baur 2014). Sexual harassment is not reported due to fear of losing one's career and therefore financial/economic security, as well as fear of personal embarrassment and professional alienation. (Crooks and Baur 2014).

Although the expression of power may not be the ultimate goal of sexual harassment, it is clearly a tool some men use as a means to gain sexual access to the women with whom they work and study (Studd 1996). However, the power hypothesis does not make any claims regarding markers of female reproductive potential (e.g., age, marital status, etc.). In addition, if power were the key motivator of sexual harassment, then women in powerful positions would also be more inclined to sexually harass, which data does not support (Studd 1996).

Conclusion

Sexual harassment is historically a concern for feminist psychologists and sociologists as a method for men to oppress, objectify, and control women's opportunities and successes. The Women's Movement of the 1960s brought sexual harassment into light as a matter of legal and social debate in efforts to achieve women's liberation and as a call for change within social structures to strive for gender equality (Rowe 1977). Women rallied for equality in the contemporary workforce, rights to participate in sports, rights for educational and professional access, and reproductive behavior. In the early 1970s, a small group of academic women agreed that sexual intimidation on the job was problematic enough to warrant a name for the behavior which encompasses unwanted male attention, flirtation, and sexual coercion of women (Brownmiller 1999). As women began to compete with men, and take on the roles once exclusively held by men, they also posed a threat to men's power in the home and in the workplace. Female competition in the workplace is an added confound

to the evolutionary perspective on sexual harassment. Harassment can occur in all workplaces, academic settings, within the military, and other social settings. It is also important to note that, although women are the predominant victims of sexual harassment, men do experience sexual harassment – usually from other men (A.W.A.R.E.; Crooks and Baur 2014).

Sexual Harassment in the Workplace

Hilda Costa

Universidade Federal do Ceará, Fortaleza, Brazil

Synonyms

[Sexual abuse in the workplace](#); [Sexual exploitation at work](#); [Workplace harassment](#)

Definition

Unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature that negatively affects an individual's employment, work performance, or work environment.

Introduction

Workplace sexual harassment in the United States is legally defined as a form of sex discrimination that violates Title VII of the Civil Rights Act of 1964, and includes unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature that negatively affects an individual's employment, work performance, or work environment (Equal Employment Opportunity Commission 2010). Although academics have often disagreed on the specific behaviors that constitute sexual harassment, research has shown that less severe forms of sexually harassing behaviors – such as remarks, jokes, looks, and gestures – are the most prevalent, whereas the most severe ones such as assault and attempted rape still remain low (Pina et al. 2009). Even though evidence is mixed about the incidence of sexual harassment, the majority of women will experience some type of sexual harassment during their working lives (European Commission 1999).

Evolutionary Perspective and Sexual Harassment in the Workplace

Many theories have been proposed in order to explain the ongoing occurrence of sexual harassment in the workplace. For example, classic explanations such as sexism, gendered environments, power misuse/abuse, and hierarchical issues (Pina et al. 2009). However, many of these explanations are just proximate pieces and cannot explain the underlying psychological mechanisms that produce sexual harassment. Applying the lens of the evolutionary perspective, we consider that although some actions at work are motivated by gaining social status, others could be about prioritizing kin, and yet others could be motivated by a need to find mates (Jonason et al. 2014). For a critical clarification, we suggest that it may be important to consider sexual strategies – along with perspectives emphasizing sexism – when trying to understand sexual harassment. Conflicts about sociosexual interactions – which are likely to be an expression of a desire to become sexually involved – are the main elements for understanding sexual harassment in the workplace (Studd and Gattiker 1991).

The differences in reproductive biology and consequently the conflict of sexual strategies would be the ultimate cause of sexual misunderstanding and harassment in any social environment (Buss 1989), including modern environments, despite deep social and technological changes. As an evolved psychological mechanism for seeking out available sexual opportunities, there is a higher tendency for males to use a continuum of aggressive tactics in order to obtain mates. So, because humans bring the same psychological mechanisms to the workplace, the observed patterns of sexual harassment are a consequence of the evolution of sex-specific opportunistic mating strategy. Thus, this may be one possible explanation regarding why sexual harassment is a chronic problem in organizations (Studd and Gattiker 1991).

Although it may be misleading to generate a typical profile of the sexual harasser and the victim based on sociodemographic characteristics,

the research literature points predominantly to men's harassment against women, with scarcely few exceptions (e.g., American Association of University Women 2001). It also tends to have a much greater impact on women, who suffer besides occupational consequences, intense negative emotional responses (sometimes similar to that experienced by victims of rape; Koss 1990). Sexual harassers appear to permeate all social strata, occupational levels (it more often involves advances made by coworkers or subordinates than by superiors; Studd and Gattiker 1991), and age categories (Pina et al. 2009).

It is important to note that there may be individual differences in personality that may further our understanding of who is more likely to engage in sexual harassment.

For example, past research has found connections between sexual harassment and callous exploitation of others and lack of empathy (Gannon et al. 2008), as well as the dark triad traits and sexual harassment tendencies (Zeigler-Hill et al. 2016). Therefore, dark personality traits are seen not just in terms of their problematic associations but also as adaptive mechanisms (Jonason et al. 2014).

Conclusion

Finally, a hypothesis based on sexually dimorphic psychological mechanisms is not the same as saying that sexual harassment is morally legitimate in any sense. We do not want our assumptions to have the effect of trivializing sexual harassment or assuming change efforts must be futile. Rather, the attempt to expand our understanding of sexual harassment is in order to examine the potential causes and develop effective solutions for such deplorable side effects of human nature (Studd and Gattiker 1991).

Definition

An individual's identification and self-definition based on the magnitude and type of intrapersonal and interpersonal attractions, desires, fantasies, and behaviors pertaining to sex, sexuality, and intimacy.

Introduction

Identity is the chosen term or terms used by an individual as a label denoting the representation of their values, beliefs, characteristics, behaviors, attractions, and roles. The construction of a personal, or ego, identity begins with two main components, distinguished by psychologist Roy Baumeister as continuity and differentiation (Baumeister 2011). Continuity refers to the ability to see oneself as fundamentally the same over time, while differentiation refers to the ability to distinguish oneself from other individuals or groups; thus, what is required for a personal identity is to see oneself as different and for that difference to be maintained over time and contexts. Prominent identity researcher, Erik Erikson, recognized adolescence as the point during which identities of all kinds begin to form. In fact, Erikson named identity formation as the critical developmental task of the teen years, as these individuals have the flexibility to explore different options for their identity before making long-term commitments, known as psychosocial moratorium (Erikson 1968). James Marcia built on this theory of identity conflict during adolescence by understanding it as a time when individuals are able to explore and commit to their identities, though some do both while others do neither, to establish an internal locus of self-definition (Marcia 1966).

Theories of Sexual Identity

There are many different types of identities that a person may have including gender, race, ethnicity, religion, culture, socioeconomic status, and sexuality. Due to the coinciding of biological,

emotional, behavioral, social, and psychological changes accompanying puberty with the identity exploration of adolescence, *sexual* identity becomes particularly salient for many individuals at this time. Sexual identity is the term chosen by an individual that they find most representative of their sexual life. While sexual identity is often conceptualized as the amount of same- and other-sex attractions, there are many facets. In fact, recent research has proposed a framework for sexual identity that encompasses the multi-dimensional nature of sexual identity for all individuals, including those who identify as a sexual majority like heterosexuals (Dillon et al. 2011). This structure for sexual identity is formed from one or more of the six bases of sexual identity: basic sexual needs, preferred characteristics of partners, specific activities or behaviors, preferred interpersonal contexts for expression, values, and preferred modes of expression (Worthington et al. 2002).

Basic sexual needs describe an individual's internal experience of sexual desire, drive, impulse, interest, and/or libido (Worthington et al. 2002). Examples of a sexual identity that centers on basic sexual needs would be asexuality or hypersexuality. This facet of sexual identity would also refer to an individual's sociosexuality, or desire for uncommitted sexual encounters, such as one-night stands (Penke and Asendorpf 2008). Preferred characteristics of partners refer to the physical, emotional, intellectual, economic, spiritual, and other characteristics that an individual is specifically sexually interested in. Examples of sexual identities centered on preferred partner characteristics would be sapiosexuality (attracted to intelligence), a "gold digger" (attracted to wealth), or a hebephile (attracted to early pubescent characteristics). Preferred characteristics of partners also refer to the preferred sex and gender of a sexually attractive partner; this is the most common basis for a sexual identity, such as lesbian, gay, bisexual, or pansexual (Worthington et al. 2002). Specific sexual activities or behaviors refer to what an individual prefers to take place during a sexual encounter. Examples of sexual identities centered on sexual behaviors would be an exhibitionist or someone classifying as

celibate. Interpersonal contexts for expression refer to how an individual prefers the dynamics of a sexual encounter with their partner or partners. Examples of sexual identities centered on interpersonal dynamics would be swingers, polyamorists, dominants, or submissives. Values refer to an individual's moral standards about what is sexually appropriate, acceptable, and desirable. Examples of sexual identities centered on values are virginity pledger or born-again virgin. Finally, modes of expression refer to the preferred way an individual articulates sexual affection and interest such as through tone of voice, eye contact, body movements, and physical touch. Examples of identities centered on modes of expression would be individuals who identify as "huggers" or "flirts" (Worthington et al. 2002).

Just as there are multiple bases for a sexual identity, an individual may have multiple sexual identities at one time, such as a BDSM practitioner and pansexual, which can overlap or be distinct. Additionally, an individual may have multiple sexual identities over the course of their lifetime, such as a woman who may have once identified as bisexual, but now identifies as lesbian. There are many factors that contribute to which sexual identities an individual adheres to at any point in their life, most importantly the individual's sense of self, micro-social contexts, and macro-social contexts (Dillon et al. 2011). The individual's internal relationship to their sexual identity is the sense of self as a sexual being formed through recognition and acceptance of one's sexuality. This sense of self can be affected by biology, early and later sexual experiences, and sexual desires and attitudes. The social context of sexual identity focuses on how the individual's sexuality is related to other people. A micro-social context of family, friends, and community influences contributions to sexual identity such as sexual values, morality, access to sexual knowledge, and sexual and gender norms. A macro-social context influences these same sexual outlooks and access on a national, cultural, or global level. Together, the micro- and macro-social contexts create an implicit or explicit sense of belonging to a sexual group based on an individual's sexual identity, be it a majority or minority

group, and allow the adopting of attitudes, beliefs, and values about the individuals and other possible sexual groups. The integration of the many facets of sexual identity existing within these contexts thus allows the development of a multi-dimensional sexual identity construct (Dillon et al. 2011).

A new, promising perspective of sexual identity, Sexual Configurations Theory (SCT), addresses this multifaceted nature of sexual identity (van Anders 2015). In SCT, individual and partnered sexualities are considered separate domains and include aspects such as individual gender/sex, gender/sex sexuality, partner number sexuality, sexual parameters (which are similar to modes of expression), and eroticism/nurturance. For each domain, an individual can place themselves on a three-dimensional spectrum, which also allows for an indication of the level of importance each facet has for them. An individual's sexual identity is thus a particular configuration of these sexual features and is not discrete or fixed, theoretically mirroring lived experiences of sexual multimodality and allowing for identities that occur at intersections with other identities, such as gender/sex, race, or age (van Anders 2015).

Commonly, though, the most salient facet of sexual identity for an individual is sexual orientation identity, particularly for people who have same-sex attractions (Savin-Williams 2009). This is also the facet that has been socially constructed as the most important aspect of our sexual identity. Sexual orientation identity is the representation label chosen by an individual to best describe their sexual relationship, or lack of sexual relationship, with others based on gender or sex, and may be anchored in the individual's sexual behaviors, attractions, fantasies, social preferences, and emotional preferences. By its nature, sexual orientation identity is formed by the socially distinguishing features of sexual preference that are unchangeable but socially consequential. The Klein Sexual Orientation Grid (KSOG), a detailed system for describing sexual orientation preferences used in academia, measures all of these components of sexual orientation in the present, as well as in the past and in an ideal

future (Klein et al. 1985). KSOG is therefore able to account for the possibility of an evolving sexual orientation identity over time, as well as acknowledging that there are many factors, including an individual's social, political, and cultural climate, which may not allow for them to fully realize their ideal sexual life. An alternative measure of sexual orientation in academia is the Kinsey Scale of Sexual Responses, which focuses entirely on attractions, as opposed to behavior or fantasies, but also allows individuals to declare varying levels of attraction to males, females, or both (Kinsey et al. 1948).

Common sexual orientation identities include, but are in no way limited to, many represented by the LGBTQ+ umbrella: lesbian, gay, bisexual, queer, questioning, asexual, pansexual, polysexual, pomosexual, and omnisexual. Additionally, there are prevalent sexual orientation identities not always included in the LGBTQ+ umbrella, such as heterosexuality or those who identify as mostly gay or mostly straight. Research on individuals identifying as mostly straight and mostly gay, in particular, has blossomed only in the last 5 years; however, their inclusion in discussion of sexual orientation identity is important due to the increasing prevalence of the label. When the option to identify as "mostly" straight or gay is presented, as opposed to simply gay, straight, or bisexual, a significant number of men and women choose those labels (Vrangalova and Savin-Williams 2012). This marked difference between the two sexuality spectrums signifies the importance of the unique and multifaceted nature apparent in sexual orientation identity – itself just one facet of sexual identity.

People with marginalized sexual identities, such as those who will eventually form sexual identities of minority or socially unacceptable groups, are more likely to explore their sexual identity than those with mainstream sexual identities, such as heterosexuals. While sexual minority adolescents begin their identity development with greater uncertainty than their sexually mainstream peers, this diminishes significantly with chronological age as more and more individuals construct a consistent and distinct sexual orientation identity (Savin-Williams 2009).

There are several academic models for the construction of sexual orientation identity, all of which begin, as most identity constructions, in adolescence. First was the Cass Model of Gay & Lesbian Identity Formation developed by Vivian Cass in 1979 (Cass 1979). This was the first normative development model proposed in a society dominated by heterosexual ideals. The Cass model is a linear stage model of sexual orientation development that takes place in six consecutive stages: identity confusion, identity comparison, identity tolerance, identity acceptance, identity pride, and identity synthesis. The first stage, identity confusion, begins the process of sexual orientation identity development by questioning the presence of sexual feelings, thoughts, and behaviors, essentially leading to the question: "Could I be gay?" Some individuals in this phase will actively choose to deny and avoid contact with or information about gays and lesbians (Cass 1979).

The second phase of the stage model is identity comparison during which the individual accepts the possibility of being gay or lesbian and starts coming to terms with the subsequent social ramifications (Cass 1979). An individual during this phase may compartmentalize their sexuality, such as by believing their thoughts, feelings, and behaviors which apply only in specific contexts and are not indicative of a consistent and persistent sexual identity. As a result of this, each individual may create or adapt a label or definition that feels most right to them at that time, but this will most likely evolve over time. During this stage, happiness, life satisfaction, and self-esteem begin to decrease, while loneliness increases, from unawareness and identity confusion (Halpin and Allen 2004).

The third stage, identity tolerance, is when the person finally recognizes that they are likely a sexual orientation minority and look for membership within the gay community, both to battle feelings of alienation and to gain greater information about and comfort with being a sexual minority (Cass 1979). It is during this stage that most individuals feel the disconnection from the heterosexual majority, which makes contacts within the gay and lesbian communities so crucial. It is

during identity tolerance that happiness, life satisfaction, and self-esteem are at their lowest, while loneliness is at its highest, among all the stages (Halpin and Allen 2004).

The goal of the fourth stage, identity acceptance, is to reach the point where there is an affirmative acknowledgment of the sexual minority orientation that is confident and optimistic, as opposed to merely tolerant (Cass 1979). Although acceptance of the sexual minority identity occurs, an individual may still compartmentalize their gay or lesbian life from other facets of their world. However, many choose, at this time, to come out to those close to them. During this stage, self-esteem begins to increase significantly (Halpin and Allen 2004).

Identity pride, the fifth stage, is, as the name implies, all about taking pride in the individual's accepted sexual minority identity. Individuals during this stage are fully out about their identity and are often actively involved in gay and lesbian communities (Cass 1979). However, Cass's theory states that as the positive assessment of a gay or lesbian identity increases, the ensuing negative opinion of heterosexual and the sexual majority increases as well (Cass 1979). The individual develops an us-versus-them mentality, seeing anything nonsexual minority with negative affect, immersing themselves in gay culture to the point of aggressively limiting contact with heterosexuals, and viewing support as only coming from the gay community. During identity pride, individual's happiness, life satisfaction, and self-esteem begin to significantly increase, while loneliness significantly decreases (Halpin and Allen 2004).

The sixth and final stage is identity synthesis. In identity synthesis the individual realizes that their sexual orientation minority identity is just one part, albeit an important part, of their multifaceted sexual and self-identity (Cass 1979). This is due to the individual being able to integrate their sexual orientation with their sexual identity and their sexual identity with all other aspects of self; therefore, sexual orientation no longer makes up the entire identity. At this point, the individual continues to be part of the gay community, but also is able to move in other spaces, and does not feel the need to categorize simply on the basis of

sexual orientation. It is during this phase of identity development that life satisfaction and self-esteem are at their highest, while loneliness is at its lowest (Halpin and Allen 2004).

Fassinger's Model of Gay and Lesbian Identity Development is an alternative model published in 1997 (Fassinger and Miller 1997). Fassinger's model, unlike Cass's, highly emphasizes the importance of cultural and contextual influences and as such delineates two processes of sexual orientation identity development: individual sexuality and social sexuality. Individual sexuality is determined by the internal exploration, awareness, and acceptance of the self's sexuality, while social sexuality is determined by perceived sexual orientation group membership – either within a small group, community, or a macro-social context. Fassinger's model is also a stage model with four distinct, linear, consecutive stages: awareness, exploration, deepening/commitment, and internalization/synthesis. Identity development begins with an awareness that individuals exist with different sexual orientations, which leads to the exploration of one's feelings to determine group membership. This exploration includes internal curiosity and questioning, as well as one's social context in relation to the gay and lesbian community. Once explored, an individual commits to their sexual orientation group, social community, and both positive aspects of identity and belonging and the negative consequences of prejudice. It is at this point that the individual's sexual orientation identity becomes the most salient facet of their identity, but eventually the individual is able to internalize their identity as important and consistent regardless of context (Fassinger and Miller 1997).

There have been several valid critiques of the models of sexual orientation development proposed thus far. Though the models' development fit those they were developed on, those people were primarily white, gay men coming out in the 1970s and 1980s in the USA. While some lesbians were also included in the creation of these models, the majority of participants in sexual identity research were male, and almost exclusively white, American, and middle-to-upper class socioeconomic status (Savin-Williams 2001).

These models were also not fit for people who identify as anything other than exclusively gay or lesbian, such as bisexual, pansexual, or asexual, though many of the experiences, such as coming out or understanding the social ramifications of having a sexual minority orientation, may still apply. Additionally, sexual minority individuals are not a homogeneous group and experience many differences in identity development over time, especially among those who may have same-sex desires, but may not adopt a culturally defined sexual identity label (Savin-Williams 2001). Even the relationship among sexuality labels has changed, for example, social stigma has, and is continuing to, shift significantly. Some other sociocultural factors that influence development yet are not accounted for by sexual orientation identity development theory, including race, socioeconomic status, education, religion, culture, gender, and ability (Kaufman and Johnson 2004).

Another critique is in the stage model aspects of the proposed identity models. There is an assumption that they are inevitable, invariable, linear, and normative. Inevitable in that all people identified as gay or lesbian must go through all the stages in the model in an invariable and linear order – that is, all the stages must happen one at a time, in the same order for every individual, unidirectionally with no back and forth or regression (Langdrige and Moon 2008). Normative in that every individual who identifies as gay or lesbian concludes in the final stage of integration, as opposed to staying in an earlier stage such as Cass model's identity pride and never moving into identity synthesis. Many people have found that these factors make it difficult for sexual identity theories to describe a variety of experiences. Because people, and their experiences, are unique, no one theory will describe all people.

Some alternatives to the sexual orientation minority theories previously discussed have been proposed. One such alternative theory is by D'Augelli (1994). This theory focuses more on the sociopolitical context of identity formation and, as such, takes a more historical viewpoint to creating a model for identity development in same-sex attracted individuals. D'Augelli's

process, unlike the linear models of Cass and Fassinger, proposes a series of six unsystematic and independent identity processes. Though this model is theoretically variable, the first process often begins with relinquishing a heterosexual sexual orientation identity label. The following five processes may happen in any order but are important to the sociopolitical context of becoming a sexual minority-identifying person: understanding and developing an individual sexual minority identity; announcing a sexual minority identity socially; coming out to important family members, especially parents; developing a relationship with a person who either affirms and/or understands sexual minority identification; and entering and feeling part of a sexual minority community. Many people experience these processes at different times and in different ways, especially given that this model focuses primarily on the relationship of one's sexual minority identity to others in the sociopolitical climate (D'Augelli 1994).

Another sexual identity development alternative is to look specifically at sexual orientation development milestones, not as a stage model, but as general guidelines for understanding normative sexual orientation identity development (Katz-Wise et al. 2016). There are five identified major sexual orientation development milestones: same-gender attractions, other-gender attractions, same-gender sexual experience, other-gender sexual experience, and sexual minority identification. While these milestones may not happen in any particular order, nor are all milestones inevitable, many individuals who go through the sexual orientation identity development process indicate the importance of their first experience of attractions toward another person (same or other sex), their first sexual experience with another person, the first questioning of their sexual orientation, the first disclosing of a sexual minority identity to others (coming out), their first romantic feelings for another person, or the first relationship (Katz-Wise et al. 2016). Statistically, there are two main groups that have evolved from research investigating sexual orientation development milestones: those that experience the first same-sex attraction during childhood and those who

experience it in adolescence (Katz-Wise et al. 2016). Predominantly, people who eventually identify as exclusively same-sex orientated tend to experience their first same-sex attractions in childhood, as well as being more likely to present as less traditionally gender conforming. Those that experience their first same-sex attraction in adolescence are more likely to identify as a non-exclusive sexual minority, such as bisexual, mostly heterosexual, pansexual, or unlabeled. Women are also more likely to experience their first same-sex attraction in adolescence and are also more likely to experience all five milestones of sexual orientation identity development – including same- and other-sex sexual experiences (Katz-Wise et al. 2016).

Due to women's unique experience, another proposed theory for development is female sexual fluidity, a theory of female sexual identity development proposed by Lisa Diamond and popularize in her book by the same name in 2008 (Diamond 2008). Female sexual fluidity is defined as "a situation-dependent flexibility in women's sexual responsiveness." This posits that it is possible for some women to experience sexual desire for men or women in specific circumstances, despite her sexual orientation identity, building off of the theory of erotic plasticity that postulates that women's sexual arousal is more affected by environment than men's sexual arousal (Baumeister 2000). This is not to say that sexual orientation does not have a biological component, as it certainly does; however, for women especially, the biobehavioral links between affectional love and sexual desire, though independent, are bidirectional. Sexual attractions are affected by both biological and sociocultural factors. Therefore, in a situation where there are strong emotional, romantic feelings, this can lead to feelings of sexual desire, even for someone who would not typically be the target for a specific sexual orientation identity. These strong feelings, both love and sexual, can lead to a change in sexual orientation identity over time, as has been found in the research (Diamond 1998). In fact, as opposed to being a transitional stage between heterosexuality and homosexuality, many women actively adopt sexual orientation identities such as unlabeled,

queer, or bisexual throughout adolescence and adulthood. While there is some new, and as yet unpublished, evidence suggesting this same relationship exists in men, but to a lesser extent, this phenomenon has been shown to exist in women over decades of research.

Female sexual fluidity as an alternative theory of sexual orientation identity development highlights that there are significant sex differences in sexual identity development – both biological and sociocultural (Diamond 2008). For example, men reach the sexual orientation development milestones earlier than women, which is certainly affected by women being sexually active and aware later in life in general, at least partially due to the sociocultural climate toward female sexuality (Katz-Wise et al. 2016). This sociocultural climate may also contribute to twice as many women reporting any same-sex sexual contact as men. Gay males also tend to feel different as children and usually identify as gay around age seventeen, after their genital experience with another person. However, lesbians, who tend to identify as gay around age eighteen, on average, don't have their first genital experience with another person until around age twenty (McClelland et al. 2015). Additionally, the timing of a man's first same-sex attraction is associated to his sexual orientation identity development; however, the quality and context of a woman's early attraction and behavior are more important. This returns to what may be a fundamental difference between male and female sexual identity – the importance of the individual and the environment.

The distinction between sexual attraction and sexual behavior is important to emphasize when discussing sexual identity. While sexual attraction and sexual identity are correlated closely with each other, they are not completely correlated with reports of sexual behavior (Chandra et al. 2013). This is perhaps because attraction often lacks coherent definition. From an academic standpoint, attraction consists of three major categories: onset of attractions, frequency of attractions, and the intensity of attractions (Savin-Williams and Joyner 2014). While sexual attraction is often synonymous with sexual orientation, sexual attraction is simply one facet of sexual orientation identity. However, sexual attraction is

better correlated with sexual identity than sexual behavior and is the preferred measurement used by academics to determine sexual interests overall for this reason. Several studies have found a substantial incongruence between the behavioral and identity dimensions of sexual orientation identity. For example, there are many individuals who identify as exclusively heterosexual who have had same-sex experiences, who identify as exclusively homosexual who have had other-sex experiences, or who identify as bisexual and have only other-sex experiences, but intense same-sex sexual fantasies (Morrison et al. 2005). In addition to being a preferred measurement tool, the three facets of attraction are more influential than sexual behavior in determining how an individual will construct their sexual identity. While sexual behavior is observed as external and context-dependent, the importance of sexual attraction in developing and defining an individual's sexual identity is a consequence of the individual's perception of attraction as a differentiating and consistent aspect of the self, the two components necessary to create a personal identity relevant to the sexual life.

Conclusion

Sexual identity is multifaceted, multimodal, variable, mutable, and highly personal. Though its unsystematic nature increased the difficulty in studying sexual identity, many researchers have dedicated themselves to understanding its foundation and development, especially during adolescence, a sensitive period for both sexual and identity development. Researchers have argued about the nature of this development, and how best to measure it, for decades, and will continue to do so for decades more. At this moment, however, we know that sexual identity, though in common parlance is focused on same- and other-sex attractions, includes facets of fantasy, desire, past behavior, current behavior, ideal behavior, sociopolitical context, romantic feelings, sexual attractions, preferred characteristics of partners, preferred number of partners, preferred levels of commitment, values and morals, and interpersonal desires. Though not every facet will be

important to every individual at every point in time and both the content and importance can change over time, each one aspect of sexual identity contributes to an understanding of a complete sexual identity.

Sexual Imprinting

Bowen Hou and Yan Wang
Department of Psychology, Fudan University,
Shanghai, China

Synonyms

Positive sexual imprinting

Definition

The process through which sexual preferences are acquired from the characteristics of the parents.

Introduction

Sexual imprinting is a special type of imprinting which is thought to be related to sexual or mate preferences of animals. As evolutionary psychology mainly focuses on behavioral traits involved with survival and reproduction, sexual imprinting has been intensively studied, especially the sexual imprinting in human beings.

In fact, sexual imprinting can be either positive or negative. Positive sexual imprinting refers to acquiring sexual preferences according to the characteristics of one or both of the foster parents. The frequently mentioned “sexual imprinting” usually refers to positive sexual imprinting. On the contrary, negative sexual imprinting refers to acquired avoidance of mating with individuals who resemble kin, which is also known as Westermarck effect. The phenomenon of sexual imprinting has been found in both nonhuman animals and humans and has brought new inspiration to the field of mate choice of animals and human beings.

The Evolutionary Function of Sexual Imprinting

Individuals may acquire preferences for specific physical traits during a sensitive period from their parents and then form the sexual preferences for the potential mate. This process has been described as sexual imprinting or positive sexual imprinting (e.g., Rantala and Marcinkowska 2011). In Immelmann’s studies (Immelmann 1972), birds such as male zebra finches tended to prefer mates that possessed the characteristics of the female bird who reared them. Similar studies have obtained the same results which verified the existence of sexual imprinting and suggest that individuals acquire sexual preferences from the one who gives them parental care rather than the birth parent when they are different (ten Cate and Vos 1999). The phenomenon of sexual imprinting occurs not only in birds but also in mammals. For example, male sheep fostered by goats appeared to be more attracted to females of the same species of their foster mother, and the effect turned out to be irreversible (Kendrick et al. 1998).

Previous studies suggested that sexual imprinting served as an important factor of species recognition (ten Cate and Vos 1999), which was also a function of imprinting. Through sexual imprinting, individuals learn the phenotype of those who rear them, and this may affect their mating process during adult period. By forming the preferences for mates according to early experience with parents, sexual imprinting may help reduce the probability of hybridization, because it enables the individual to find a conspecific mate when they become an adult.

Evidence for Sexual Imprinting in Humans

Recently, more and more studies have suggested that sexual imprinting also influences the process of human mate selection. The major topic of discussion would be the similarity of facial traits between one’s spouse and the opposite-sex parent. For instance, Bereczkei et al. (2002) asked participants to rate the similarity of a set of photos, among which the photos of wives and their mothers-in-law are included. The results showed that wives and their mothers-in-law are more easily to be matched correctly than by chance, indicating that men were more likely to choose

women who possessed the facial characteristics of their mother as wives. Similar preferences were also found in women, even if the woman was adopted as a child (e.g., Wiszewska et al. 2007). Furthermore, recent study showed that the preference for parents' facial traits can be found in 9-year-old children, particularly when parent-child relationship quality is positive (Vukovic et al. 2015).

Other evidences supporting the sexual imprinting in humans include the hair and eye color of one's partner and opposite-sex parent (e.g., Little et al. 2003). Besides, imprinting-like effect has been found in preferences for female physical characteristics such as breast size and shape in both heterosexual men and homosexual women (Valentova et al. 2017).

In addition, it is inferred that information related to age of parents can also be learned through sexual imprinting during early experience. Ages of women's actual partners and their parents turned out to be correlated (Wilson and Barrett 1987). In later experiments, participants born to older parents were more attracted to older faces (Heffernan and Fraley 2013), suggesting that early interaction with parents may play a role in shaping later mate preferences.

Conclusion

Sexual imprinting was first found in animals such as birds and mammals, describing the phenomenon that individuals would show sexual preferences for those who possess the characteristics of their parents. Then similar behavioral patterns were found in humans in several aspects, including the most discussed preference for facial traits. Although some of the research findings may have alternative explanations, sexual imprinting is still of great significance in predicting human mate selection, and more studies are needed to establish the theory of human sexual imprinting.

Sexual Infidelity Versus Emotional Infidelity

Carlota Batres

Department of Psychology, Franklin and Marshall College, Lancaster, PA, USA

Synonyms

Cuckoldry; Emotional unfaithfulness; Sexual unfaithfulness

Definition

Sexual infidelity is unfaithfulness that involves a sexual component (e.g., engaging in sexual intercourse), and emotional infidelity is unfaithfulness that involves an emotional component (e.g., forming an emotional attachment).

Introduction

Both men and women exhibit negative emotions over both sexual and emotional infidelity (Sabini and Green 2004). However, research has found that men and women exhibit different levels of distress depending on whether the infidelity is sexual or emotional (Buss et al. 1992; Edlund et al. 2006; Fernandez et al. 2006; Kuhle 2011; Shackelford et al. 2002).

Evolutionary View on Sexual Versus Emotional Infidelity

From an evolutionary perspective, men and women face different adaptive problems, and therefore level of distress over infidelity should correspond to which risk is greatest for each sex (Buss 2005). Due to paternity uncertainty, males risk channeling their efforts into offspring that may not be their own. Thus, being more distressed over sexual infidelity would help guard against being cuckold. On the other hand, women risk

losing the aid and resources of a partner to someone else. Thus, being more distressed over emotional infidelity would help guard against losing partner investment.

There is research that provides evidence for differing levels of distress in men and women over sexual versus emotional infidelity (Buss et al. 1992; Edlund et al. 2006; Fernandez et al. 2006; Kuhle 2011; Shackelford et al. 2002). For example, Buss et al. (1992) asked participants to think about a serious committed relationship and then asked them which of the following two scenarios would upset them more: “Imagining your partner forming a deep emotional attachment to that person” or “Imagining your partner enjoying passionate sexual intercourse with that other person.” Men were more likely to report greater distress over sexual infidelity, whereas women were more likely to report greater distress over emotional infidelity. Physiological responses were also found to follow the same pattern (Buss et al. 1992). Men showed greater electrodermal activity when imagining sexual infidelity, whereas women showed greater electrodermal activity when imagining emotional infidelity.

Likelihood of forgiveness and recall of cues have also been found to be influenced by the type of infidelity (Schützwohl and Koch 2004; Shackelford et al. 2002). With regard to likelihood of forgiveness, Shackelford et al. (2002) found that men were more likely to indicate that they would find it more difficult to forgive sexual infidelity than emotional infidelity, whereas women were more likely to indicate that they would find it more difficult to forgive emotional infidelity than sexual infidelity. With regard to recall of cues, Schützwohl and Koch (2004) found that men preferentially recalled cues to sexual infidelity, whereas women preferentially recalled cues to emotional infidelity.

Conclusions

There is much evidence supporting the evolutionary view that distress to infidelity is a sexually dimorphic adaptation (Buss et al. 1992; Edlund

et al. 2006; Fernandez et al. 2006; Kuhle 2011; Shackelford et al. 2002). However, it should be noted that the sex difference has failed to replicate with certain samples (e.g., Carpenter 2012; Sabini and Green 2004). Additionally, alternative accounts for such effects have been proposed (Harris 2000). For example, Harris (2000) proposes that men are simply more reactive to sexual stimuli than emotional stimuli and that women have greater ease at imagining emotional stimuli than sexual stimuli. Therefore, future research is still needed but the existing literature has given us great insight into these differing forms of infidelity.

Sexual Intercourse: Genital contact, especially the insertion of the penis into the vagina, perhaps followed by orgasm.

Introduction

Poets and novelists have always been fascinated by sexual passion but until recently scholars had conducted very little scientific research on the topic. Such research was considered taboo, trivial, vulgar, and unscientific. One exception to this prohibition was evolutionary theory. Since Darwin's (1859/1988) classic *The Origins of Species*, anthropologists have been interested in how men and women go about selecting sexual partners and mates, what people prefer in potential sex partners, whether or not men and women differ in their desire for sexual intercourse, and how often people of various ages, genders, and ethnicities engage in sexual intercourse. Evolutionary psychologists provided a scientific rationale for such investigations and made it clear that such investigations were vitally important, since such preferences shaped the future of humankind. Let us now consider their findings.

Who Do Men and Women Prefer for Sexual Partners?

Evolutionary psychologists contend that there are cultural universals in what men and women desire in a mate and sexual partner. This contention is supported by a landmark cross-cultural study conducted by Buss (1994), who asked more than 10,000 men and women from 37 countries to indicate what characteristics they sought in potential mates. These people came from a variety of geographic, cultural, political, ethnic, religious, racial, economic, and linguistic groups. Buss found that, overall, the single trait that men and women in all societies valued most was "mutual attraction-love." After that, people cared next about finding someone who possessed a dependable character, emotional stability and maturity, and a pleasing disposition.

People also tend to end up with mates and sexual partners who are very similar to themselves. This is called assortative mating. Buss and Barnes (1986) observed that the number of traits on which couples were matched was "staggering." Couples show such matching for age,

race, religion, personality dispositions, attractiveness, drinking, height, weight, smoking, interests, attitudes, and a host of other variables (see also Hatfield and Rapson 1993; Hatfield et al. 2012 for a list of universally desired characteristics).

Although evolutionary psychological research has provided fairly robust explanations for mate preferences, research so far has failed to sufficiently infer mating behavior for mate trait preferences. Conroy-Beam and Buss (2016) found that mate preferences predict actual mating decisions using evidence from computer simulations and real-world couples. Conroy-Beam and Buss showed that mating preferences strongly predict mate selection in preference-driven simulations but not in simulations in which mate selections were random. Moreover, mate preferences significantly predicted mate decisions in real-world couples. These conclusions offer support for the notion that mate selection is a cause of stated mate preferences rather than a consequence of the individual updating his/her mate preferences to fit the chosen mate.

As evolutionary theory would suggest, Buss (1994) found some marked differences in what men and women want in mates and sexual partners. As discussed in earlier entries, men and women must employ somewhat different strategies in order to maximize their genetic contributions to the next generation. As predicted, men tended to care more about the physical appearance and youth of their partners than did women; women tended to be more insistent that their mates possess high status and the resources necessary to protect themselves and their children.

Petersen and Hyde (2010) conducted a meta-analysis of research into gender differences in sexuality, conducted from 1993–2007. They analyzed the impact of gender on 30 sexual attitudes and sexual behaviors for men and women from 87 countries and 6 continents. They included 834 individual samples and 7 large national data sets in their analyses. Consistent with evolutionary psychology, they found that men did indeed report more permissive attitudes toward casual sex and slightly more sexual experience than did women. However, they also found that (1) in nations and ethnic groups with greater gender

equality, people display smaller gender differences in attitudes and behaviors than do people from more traditional nations and ethnic groups, (2) over time, many traditional gender differences seem to be disappearing, and (3) in all nations, those gender differences in sexual attitudes and behaviors which did still exist were surprisingly small. Exceptions were in the incidence of masturbation, pornography use, attitudes toward casual sex, and the incidence of participating in casual sex – all of which yielded medium effect sizes. As predicted, men possessed more permissive attitudes toward casual sex and engaged in slightly more casual sexual behavior than did female participants.

Appearance

In choosing sexual partners, people tend to focus on the potential partner's physical appearance. Men desire young and beautiful women with symmetrical faces, smooth skin, medium to large plump breasts, a 7:1 waist to hip ratio, rounded buttocks, and long shapely legs. Women desire men with strong masculine features, a V shape (muscular shoulders with small hips) and a large penis (see Singh 1995). These traits, for both sexes, are overt indications of the potential mate's physical health and reproductive ability.

Evolutionary psychologists have focused on primary and secondary sexual characteristics. They ask: Why do penises, vaginas, and breasts have the size and shape that they do? When compared to other primates, why do humans have larger penises and vaginas than other hominoids (apes)? (Dixon 2009).

Evolutionary theorists have argued that breasts evolved as a way to signal to men that a woman was youthful and nutritionally advantaged, and thus would be a promising mate. A paper in the *Proceedings of the Royal Society* by Jasienska et al. (June 22, 2004) reported that women with large breasts and narrow waists possess higher fecundity (as measured by daily levels of 17- β -oestradiol and progesterone).

Do men in various societies consciously recognize these cues? Maybe not. In a study of

191 cultures, Ford and Beach (1951) found that in only 13 of these cultures was breast size considered important: nine preferred large breasts, two preferred long pendulous breasts.

Why is the human vagina so large, compared to other primates? Humans are unique in that they come into life prepared to fit into their environment. Infants take longer in gestation, have larger brain size, and larger newborn body size than their peers. That means that women's vaginas and birth canals must be unusually large to accommodate the infant (Mautz 2012).

Given the size of women's vaginas, men must compensate by having larger penises (in girth). When erect, it measures between 5 in. and 6 in., on average, and about 5 in. in circumference. That is twice as big as that of chimps, for example (Bering 2012). Women prefer a large phallus in men. When women are shown life-sized projections of naked men, they say the ones with bigger organs are more attractive (Mautz 2012).

Why is the penis shaped as it is? Gordon Gallup concluded that the oddly shaped member, with the bulbous head, coronal ridge, and long, rigid shaft is designed to "shovel out" the sperm of previous sexual partners and deposit their own. In research with various types of penises, with different shapes, he finds that the male penis is especially efficient at this task.

How Often Do Men and Women Have Sexual Intercourse?

The physiological responses during sexual stimulation are fairly similar for both men and women. There are four phases in the human sexual response cycle (Masters and Johnson 1966.)

- During the excitement phase, the body prepares for sexual intercourse. Heart rate and breathing rate increase and blood pressure rises. Men and women experience a "sex flush" on the face and upper body. Typically, a woman's vagina becomes lubricated and her clitoris becomes swollen. A man's penis becomes erect.

- During the plateau phase, heart rate and muscle tension increase further. A man's urinary bladder closes to prevent urine from mixing with semen. A woman's clitoris may withdraw slightly and there is more lubrication, outer swelling, and muscles tighten and reduction of diameter.
- During the orgasm phase, breathing becomes extremely rapid and the pelvic muscles begin a series of rhythmic contractions. Both men and women experience quick cycles of muscle contraction of lower pelvic muscles and women often experience uterine and vaginal contractions; this experience can be described as intensely pleasurable, but roughly 15% of women never experience orgasm and half report having faked it.
- During the resolution phase, muscles relax, blood pressure drops, and the body returns to its resting state. After this period, men (and some women) are no longer able to experience an additional orgasm, or multiple orgasms soon after the first.

According to Masters and Johnson (1966), men are physically incapable of bypassing the resolution phase. Women, however, are able to enter the orgasm phase, return to the plateau phase, then continue to the orgasm phase again. The ability to circumvent the resolution phase allows women to experience multiple orgasms in one sexual episode.

In 1994, Laumann and his colleagues released data from a survey of Americans asking about their sexual practices. Most previous studies were limited to small samples of Americans, based on convenience samples rather than random samples. Laumann et al.'s study was the gold standard in that it used a large random national sample. Similar scientific studies exist for other cultures.

When people speak of "sexual behavior" they might mean marital partners, a dating couple, or casual sex. It may mean vaginal sex, oral sex, anal sex, or masturbation (which evolutionary psychologists say should be less attractive than sexual intercourse, since it does not give people a chance to contribute to the gene pool). It could be

heterosexual, homosexual, one-on-one sex, or group sex. Because of space limitations, we will present only a few of Laumann et al.'s (1994) findings. People interested in more complete data may consult the surveys we have referenced.

- Most married couples have intercourse seven times a month (Laumann et al. 1994; Call et al. 1995; Donnelly 1993).
- There is tremendous variability in how often couples have sexual intercourse in marital relationships. Some couples are celibate or have intercourse very infrequently while others have sex daily. Cathy Greenblat (1983) interviewed 80 people who had been married 5 years or less. She found that couples reported having intercourse ranged from once a month (12 times a year) to 540 times a year.
- Sexual activity declines with age (specifically from 44 to 72). Factors responsible for the decline are changes in marital health, happiness, and poor physical health (Karraker et al. 2011).

Conclusion

Evolutionary psychology has sparked a great interest in human sexuality. In recent years, sexologists have accumulated a great deal of information on the ability of social psychologists and evolutionary theorists to predict who, what, why, and when people engage in sexual intercourse.

Definition

Men's sexual jealousy is an evolved emotional response to a real or perceived threat of a partner's sexual infidelity. It is a functionally flexible response that serves to motivate men to engage in mate-guarding behavior designed to deter intrasexual rivals and to maintain valued relationships.

Introduction

Over evolutionary history, human men have recurrently faced the challenge of finding and securing viable mating partners. Although humans evolved to form successive long-term relationships with one mate, infidelity has also been a recurrent theme in our evolutionary history.

In order to maintain their mateships, men would have had to fend off same-sex rivals, as well as signal to their partner their level of commitment to her. Likewise, it would have been crucial for men to ensure that their partners remained faithful to them. The fact that fertilization of the sperm and ovum takes place internally within the women's reproductive tract means that men, unlike women, can never be certain that the children they invest in are genetically theirs. The potential for a female partner to commit infidelity results in *paternity uncertainty* for men, which translates into a threat to men's reproductive success (Daly et al. 1982; Symons 1979). Thus, it would have been advantageous for men to have a means of identifying potential rivals, showing commitment to their mates, and remaining vigilant to suspected infidelity. Jealousy involves a constellation of emotions and behavior which have been argued to help in coordinating these interrelated efforts.

Jealousy has been defined as a distinct, yet complex, aversive emotional response to a real or imagined threat to a valued relationship (Buunk et al. 2008; Daly et al. 1982). Two basic types of jealousy have been identified which correspond with two kinds of betrayal one might experience in the context of a romantic relationship. *Sexual jealousy* is evoked in response to an actual or perceived threat of sexual infidelity, where a person may be having sexual relations with someone other than their primary partner (Buss 2013). In contrast, one may believe that their primary partner is forming a deep emotional romantic bond with someone outside of the relationship and committing emotional infidelity, which in return can elicit *emotional jealousy*. Over evolutionary time, both ancestral men and women have had to maintain mating relationships; thus, in contemporary society, men and women do not differ in the overall frequency or intensity of their jealousy (Goetz et al. 2008). However, a sex difference does emerge in regard to the two types of jealousy (sexual and emotional) owing to the differential *adaptive problems* – challenges that impact an organism's ability to reproduce (e.g., gaining access to mates) – faced by ancestral men and women (Symons 1979).

Ancestral women, given their higher obligatory parental investment (e.g., gestation, child-bearing, lactation), have primarily faced the adaptive problem of securing paternal investment for their offspring (Buss 2012). As a consequence, women demonstrate a heightened sensitivity to cues of emotional infidelity, which may signal the loss of parental resources. In contrast, ancestral men have principally faced the problem of paternity uncertainty, resulting in a lower threshold for cues to sexual infidelity. The totality of evidence to date supports the hypothesis that men express a heightened response to sexual infidelity in comparison to women, whereas women are more distressed by emotional infidelity in comparison to men (Frederick and Fales 2016). Because men, unlike the males of most other mammalian species, invest relatively heavily in their offspring, we expect that they should be particularly sensitive to signals associated with the misdirection of resources toward genetically unrelated offspring (Buss 2012).

A meta-analysis of 50 studies indicated that 24 % of women reported engaging in extramarital sexual activities (Tafoya and Spitzberg 2007). Globally, between 1.7 and 29.8 % of men are unwittingly raising children that they are not the genetic fathers of as a result such infidelity (Anderson 2006). *Cuckoldry*, unknowingly raising a genetically unrelated offspring, remains an issue pertinent to men's reproductive success. For men, a partner's sexual infidelity would have posed a major threat to their reproductive potential. For instance, unknowingly fathering a rival's child could have resulted in squandering parental investment resources, failing to benefit from a female partner's maternal effort, an opportunity cost of not being able to pursue other mateships, and becoming vulnerable to reputation damage, which could influence one's status and attractiveness as a mate (Goetz et al. 2008).

Jealousy as an Adaptation

Evolutionary psychologists have hypothesized that jealousy is a functional emotional adaptation that evolved to solve recurrent problems related to

reproduction (Buss 2013). From this perspective, it has been argued that jealousy can (1) alert an individual to threats to a valued relationship, (2) be evoked in the presence of same-sex competitors who may be interested in mating with one's romantic partner, and (3) motivate behavior meant to deter partner infidelity and relationship abandonment. As an adaptation, this means that jealousy has specific inputs, if/then decision rules, and behavioral outputs that collectively may benefit reproductive success.

Threats to a valued sexual or romantic relationship can derive from sources external to the dyad, such as a *mate poacher* who intrudes on an existing romantic relationship in an attempt to steal one's partner for either short-term copulation or to form a long-term romantic relationship. The presence of mate poachers is a common adaptive problem faced by men, because it may signal the potential loss of valued reproductive sources. In one study, it was found that approximately 60 % of men have admitted to having tried to entice another's mate into a committed relationship (Schmitt and Buss 2001), with 35 % of these men reporting that they had been successful in poaching the desired mate. Furthermore, despite expected cross-cultural variability, evidence of mate poaching has been discovered in 53 nations around the world (Schmitt 2004).

Cues to threatened stability of the romantic relationship can also derive from the dyad itself, such as when one's mate displays signs of disinterest or cues to their potential infidelity (Buss 2012). Sexual jealousy resulting from any of the aforementioned inputs may promote specific behavioral outputs that serve to maintain access to a mate, deter intrusions of same-sex rivals, and prevent a female partner from defecting from the mateship. Collectively, these actions have been termed *mate-guarding* behavior, which can range from pointing out a competitor's flaws to physically attacking another man for flirting with one's partner (Buss 2012). Notably, men's sexual jealousy has been argued to constitute the focal psychological mechanism that coordinates various mate-guarding behavior following a perceived threat to the valued relationship (Buss,

Larsen, Westen, and Semmelroth, 1992. Daly et al. 1982; Symons 1979).

Amid a chaos of conflicting social signals and cues, however, deciphering when sexual infidelity may be afoot and which intrasexual rivals pose a threat to a valued relationship is a challenging endeavor, especially when considering that the perpetrators of sexual infidelity are frequently trying to conceal their deception. These signals are often intentionally muted, such as an unfamiliar scent or an unexplained absence, which may or may not be indicative of infidelity, thus resulting in a *signal detection problem* (Buss 2012). A critical function of men's sexual jealousy is to render him more sensitive to these signals. Consider also that jealousy can be quite costly for a mateship if misdirected or unrestrained. A woman may leave her partner who falsely accuses her of cheating for a more trusting companion. Likewise, if consistently the target of *delusional jealousy* – denoting irrational and unfounded accusations about a partner's fidelity – she may defect from a relationship in search of a more emotionally stable mate, a highly valued trait for women within the context of long-term romantic relationships (Buss 2012). Furthermore, jealousy and mate-guarding efforts necessarily involve the expenditure of resources that could be allocated elsewhere, such as acquiring food and parental investment (Graham-Kevan and Archer 2009). Thus, we would expect jealousy to be functionally flexible, to produce a behavioral response based on the perceived seriousness and likelihood of losing a mate (Buunk et al. 2008).

Men's Sexual Jealousy and Aggression

Sexual infidelity can be a particularly potent stimulus for the expression of rage and anger, which tend to be directed toward same-sex rivals and/or to the romantic partner. Studies show that men's sexual jealousy is a leading cause of intimate partner violence, such as battery and spousal homicide, which is argued to constitute a strategy used by men to limit a female partner's sexual behavior (see Goetz et al. 2008). As deplorable and damaging as this behavior is, violence and

aggression might constitute evolved responses to several different but interrelated survival and reproductive problems that ancestral humans likely encountered with some consistency. For instance, aggression could have functioned to defend against an attack, to co-opt the resources of another, or to increase one's status within a social hierarchy (Buss 2012). Within the context of romantic relationships, aggression has been argued to serve three important functions: (1) to deter intrasexual rivals from pursuing one's partner, (2) to prevent long-term relationship partners from committing sexual infidelity, and (3) to reduce the probability that a partner may defect from a valued relationship (Buss 2012). In this way, aggression constitutes the context-specific behavioral output of jealousy that manifests as a range of different mate-guarding tactics designed to retain access to a desired mate, while deposing intrasexual rivals and deterring one's mate from defecting from the relationship.

Detering intrasexual rivals. The costs inflicted on an intrasexual rival could range from derogating a competitor by pointing out their flaws to using physical force to hurt or damage them and perhaps even to kill the rival. Spreading gossip about a potential competitor's imperfections constitutes a form of *indirect aggression*, where the perpetrator seeks to harm the target while simultaneously trying to conceal their intent (Vaillancourt 2013). Indirect aggression can be a useful tactic because it tends to be obscure and carries a lower probability of verbal or physical retaliation (Buss 2012). In contrast, *direct aggression*, such as punching another man who flirts with one's romantic partner or verbally threatening a rival, is conspicuous in its intent. Because men have evolved to compete with same-sex rivals for access to women, they are more often the perpetrators and the recipients of direct aggression (Archer 2004). Homicide data demonstrates that cross-culturally men kill other men at a much higher rate than women kill other women (see Goetz et al. 2008). Moreover, young boys tend to be the instigators and the victims of physical bullying (e.g., being hit) more often than girls (Swearer et al. 2010). In adult men, being unmarried and unemployed and thus lacking resources

which would benefit procuring and maintaining a mate are characteristic of both the victims and the killers involved in intrasexual homicide (see Goetz et al. 2008).

Preventing and anticipating a partner's sexual infidelity. One troubling reaction to suspected or actual sexually infidelity is men's use of intimate partner violence, which can take several forms (Arnocky et al. 2015). For instance, men may use *psychological aggression* such as attempting to reduce their female partner's self-esteem, perhaps in order to decrease how attractive and desirable she feels to members of the opposite sex (Arnocky et al. 2015). Men may also forcibly initiate sex or emotionally manipulate a partner into having sex (i.e., *sexual coercion*) if they are suspicious or know of their partner's sexual infidelity. Forced in-pair copulation in nonhuman animals follows a similar pattern, occurring more frequently after female sexual infidelity in some species (see Goetz et al. 2008). It has been argued that because sperm can survive in a women's reproductive tract for up to 5 days, inseminating a female partner can allow for one's sperm to either compete with or through the act of sexual intercourse to displace, a rival's semen. Importantly, the behavioral manifestation of jealousy does not require or imply conscious deliberation (Symons 1979). Rather, jealousy seems to motivate behavior on an implicit, nonconscious level (Buss 2012).

Men may also engage in acts of violence to prevent their partner from defecting from the dyad. This may at first seem counterintuitive; however, research has shown that women who leave their husbands are at a higher risk of being pursued, threatened, and assaulted compared to those who remain in the mateship (see Goetz et al. 2008). Shields and Hanneke (1983) reported that women who had been sexually unfaithful to their husbands were at an increased risk of battery and physical and/or sexual abuse.

In conjunction with sexual jealousy, men's feelings of anxiety also share an important link with anticipated infidelity and intimate partner violence. In many mammalian species, including humans, anxiety has been associated with aggressive behavior, and men who exhibit higher levels

of anxiety have been shown to engage in more relational aggression directed toward their intimate partners (see Arnocky et al. 2015). Interestingly, Arnocky and colleagues (2015) found that self-reported feelings of anxiety mediated a range of behavior constituting intimate partner violence such as physical, psychological, and sexual aggression in male undergraduate students. A mediating variable is one that explains the relation between two other associated variables. Men's sense of anxiety can be precipitated by feelings of uncertainty about their partner's faithfulness, and research has shown that men tend to overestimate the probability that their partner is going to or has committed sexual infidelity (Paul and Galloway 1994). This bias may however be functional, as it could serve to arouse men's suspicions, incite sexual jealousy, and motivate mate guarding and intrasexual competition, potentially allowing men to retain valued reproductive resources.

Factors that Influence the Intensity of Jealousy and Aggression

The context specificity of sexual jealousy, owing in part to its costly expression, means that individual differences likely modulate the intensity of men's jealousy and mate-guarding efforts. One such individual difference lays in the mate-value characteristics of an intrasexual rival, such that high-mate-value men represent a stronger threat to a valued relationship and should serve as a potent trigger for men's jealousy. Logically, these characteristics should also correlate with the traits that women find most desirable and attractive in a male partner. When asked to rank the qualities in a potential rival that would be most distressing, men from the Netherlands, Korea, and America consistently responded that it would be upsetting if a rival surpassed them in regard to financial prospects, occupation, and physical strength (Buss et al. 2000). Similarly, Dijkstra and Buunk (2002) found that when asked about a rival to whom one's partner might feel attracted, men, more than women, reported increased jealousy when the rival was high in social dominance,

physical dominance, and social status. In a study of participants in Argentina and Spain, Buunk and colleagues (2011) found that men, relative to women, experienced more jealousy when their rival was more physically dominant.

This research suggests that strong, dominant, physically attractive, financially secure, and high-status rivals are of particular concern to men in committed relationships. Unsurprisingly, these are among the very same qualities that women tend to seek out in sexual partners (Buss 2012). Research on individual differences among successful versus unsuccessful mate poachers also corroborate these findings. Effective male poachers tend to be attractive, tall, and have higher levels of self-esteem (Schmitt and Buss 2001; Sunderani et al. 2013), characteristics that denote high mate value which concerns one's desirability to members of the opposite sex (Buss 2012). Thus, high-mate-value rivals pose a particularly salient threat to men's mating success, and jealousy is more often experienced in their presence, relative to lower-mate-value rivals.

Similarly, men are expected to guard more intensely women of higher reproductive value because they are more desirable to members of the opposite sex as a mate and will more frequently be the target of mate poaching efforts (Sunderani et al. 2013). For instance, a woman's reproductive value declines as she ages from young adulthood onward, and it has been shown that men tend to engage in more mate-guarding behavior and more spousal violence (see Graham-Kevan and Archer 2009) toward younger partners than older partners. Flinn (1988) reported that men living in a Caribbean village, who were partnered with pregnant women (and thus unable to conceive at the time of study), spent less time with, and were less aggressive toward, their partners in comparison to men partnered with *fecund* (i.e., having higher reproductive potential) women. Men have also been shown to experience more jealousy and to guard partner's more fiercely around ovulation, the point of peak fertility across the female menstrual cycle (e.g., Gangestad et al. 2002). This demonstrates that, although ovulation is cryptic, men are able detect the subtle cues that emerge around ovulation to gauge a

women's fertility status. These signals may range from changes in body odor to differences in vocal pitch (Buss 2012).

Not all men, however, are equally concerned with or capable of establishing and maintaining long-term committed relationships, which results in differences in the expression of sexual jealousy and mate-guarding behavior. Some men effectively exploit short-term sexual relationships because they possess characteristics that connote genetic quality such as height, dominance, muscularity, and facial symmetry that are valued by women for their potential offspring (Buss 2012). These traits also reflect men's mate value (Symons 1995). High-mate-value men, in comparison to their lower-mate-value counterparts, are more sexually precocious, go on more dates, and have more sexual partners throughout their lifetime; however, they are also more likely to commit sexual infidelity (Buss 2012). Unsurprisingly, these men have been found to have a high *socio-sexual orientation*, which denotes more liberal sexual attitudes and behavior, requiring less love and commitment prior to entering into a sexual relationship (Clark 2006). Furthermore, taller men are, on average, less jealous than their shorter counterparts and experience less jealousy when confronted with socially influential, physically dominant, or physically attractive same-sex rivals (Brewer and Riley 2009; Buunk et al. 2008). Taller men have also been found to engage in less mate retention behavior overall (Brewer and Riley 2009). These findings demonstrate that high-mate-value men express less jealousy and engage in less mate-guarding behavior because there is a lower probability that they will lose their mate to a rival. These men are also more successful at procuring and establishing relationships resulting in a lower cost of mate desertion.

Lower-mate-value men are "competitively disadvantaged" having lower attractiveness, social competence, and financial prospects, leaving them at a greater risk of cuckoldry and mate defection (Figueredo and McCloskey 1993). Because these men face a larger cost associated with a partner leaving the mateship, they are likely to employ more direct, violent, and damaging forms of mate-guarding behavior in their

relationships. Indeed, men lower in mate value have been found to use more cost-inflicting mate retention tactics (Miner et al. 2009), as well as more controlling behavior and physical aggression directed toward their romantic partners (Graham-Kevan and Archer 2009). Men lower in mate value have been shown to experience more sexual jealousy at the prospect of sexual infidelity, and this jealousy has been shown to predict violence against intimate relationship partners (Cousins and Gangestad 2007). Also, men who are more invested in their relationships, as indicated by a higher degree of relationship satisfaction, have been found to exhibit more jealousy when subliminally primed with words relating to rival mate-value characteristics (especially with respect to social dominance; Massar et al. 2009).

Conclusion

Mixed findings have been reported for the association between jealousy and relationship longevity (e.g., Sheets et al. 1997), which seems to weaken the evolutionary logic of jealousy's adaptive benefits. However, it may not be the general tendency to become jealous that is important, but rather how this signal is interpreted by the recipient (i.e., the romantic partner), that determines its efficacy in solving adaptive problems. It has been shown that a partner's jealousy increases our confidence in their romantic commitment and provides reassurance of their in-pair attraction, which is positively associated with relationship stability (Sheets et al. 1997). Despite the fact that jealousy tends to produce an immediate negative response, its accompanying verbal and behavioral reassurances can help maintain long-term relational commitments. Men are particularly sensitive to cues of sexual infidelity in their romantic partners because, relative to other mammalian species, they invest heavily in their offspring and have recurrently faced the problem of paternity uncertainty over evolutionary time. Sexual jealousy is a specific emotional response to the threat of sexual infidelity, which serves to motivate mate-guarding behavior such as aggression directed toward one's partner and/or an interested

mate poacher. Despite the dangerous and damaging manifestations of excessive jealousy, contextually appropriate experiences and expressions of this emotion may have helped to solve a crucial reproductive dilemma for ancestral men: ensuring paternity by maintaining and defending valued relationships (Buss 2013). An evolutionary approach in no way justifies the deplorable manifestation of jealousy in society, such as men's use of intimate partner violence. It does however address the ultimate, root causes of this emotion and provide insight into when and in whom the more damaging behavioral output of jealousy is more likely to emerge.

Sexual Jealousy Among Women

Ana Maria Fernandez

Escuela de Psicología, Universidad de Santiago de Chile, Santiago, Chile

Synonyms

Female jealousy; Women romantic jealousy

Definition

Sexual jealousy is a strong emotional reaction evoked by a perceived threat or the actual loss of a valued romantic partner (Buss 2013a). Sexual jealousy activates mate retention/guarding, as well as intrasexual competition behaviors (Buss 2013b; Buunk and Fisher 2009), which are deeply rooted in the adaptive problems that parental investment imposed on women and men throughout evolution.

Introduction

The study of sexual jealousy as an evolved psychological feature of the human mind began with the seminal work of Trivers (1972), whereas specific predictions regarding sex differences in the function of jealousy were advanced by Symons (1979) and Daly et al. (1982), to become later

embedded in a bigger theory of human mating by Buss (1989). The observation of mate retention behaviors, as well as competitor derogation, was also integrated into the bigger picture of sexual strategies theory (Buss 2013b), while the inquiry into the characteristics of rivals that strongly evoke jealousy were incorporated by Dijkstra and Buunk (2002). Accordingly, evolutionary psychology proposes that jealousy was retained in our species given its adaptive value throughout the Pleistocene, otherwise it would not have been selected and passed on to the present day (Cosmides and Tooby 2013). Finally, the specific tactics that underpin women's sexual jealousy as well as the investigation of female intrasexual competition were incorporated to the field by the research of Campbell (2004) and Fisher (2004).

The origin of women's sexual jealousy has its roots in biological sexual asymmetries in parental investment (Trivers 1972). Women's large investment in offspring causes them to be highly demanding in terms of courtship and signals of commitment in mating and pressuring men into ensuring a high rate of investment in child rearing. In contrast, men center their reproductive efforts in preventing cuckoldry and attaining highly fertile partners (Buss 2013a). Some have proposed that conflicting interests among the sexes have led men and women, through sexual selection, to the coevolution of psychological features that are preferred by the opposite sex. Men's and women's expectations pressure the opposite sex into reciprocal equilibrium in order to fulfill their common reproductive goals or lead to negotiation and recalibration of their needs in the opposite sex according to the benefits attainable on their mutual mate choice (Conroy-Beam et al. 2015). However, relationships are a dynamic process in which social contracts can be violated by a cheating partner. Within this scenario, an effective mechanism to prevent cheating by a partner is sexual jealousy.

The function of the sexual jealousy adaptation is protecting a mating relationship from interlopers, motivating guarding strategies directed at the partner, and aggressive/distancing behaviors directed at the rival (Al-Shawaf et al. 2015; Buunk and Fisher 2009). There are asymmetries between

the sexes in the specific situations that evoke this emotion (Buss et al. 1992), as well as the features of rivals that trigger sexual jealousy more strongly (Dijkstra and Buunk 2002).

One of the most important findings regarding the evolutionary approach to human jealousy are sex differences in the adaptive problems surrounding reproduction, which underlie the specific challenges to the pair-bond that activate jealousy in women and men (Buss et al. 1992). As parental investment theory states: women have the biggest share of biological costs in reproduction and therefore exert pressure on men to contribute extended commitment and resources in parenting. This dynamic in which men and women receive equal benefits from reproduction in a pair-bond with unequal investment is a central adaptive problem for women. As a result, women's sexual jealousy is triggered more strongly than men's when faced with the threat of their partner diverting resources, love, and/or commitment toward another woman. This has been termed *emotional jealousy*. Men face a different adaptive problem, namely, cuckoldry. A woman's sexual infidelity may result in her partner's extended investment benefitting another man's child and not his own offspring, reducing his fitness. This has been labelled *sexual jealousy*, which underlies the increased experience of male jealousy compared to women's, when faced with the possibility of their partner being sexually unfaithful (Sagarin et al. 2012).

Much of the literature in evolutionary psychology has explained male sexual jealousy as being directed at preventing cuckoldry. In its most extreme form, this motivation can lead to men's aggression toward a rival or a potentially cheating partner and even the homicide of a young unfaithful woman and/or her lover (Busche et al. 2013; Daly et al. 1982).

Female sexual jealousy can also lead to emotional distress, as well as the use of mate retention tactics and aggressive behavior directed against the rival or the cheating partner. However, sexual jealousy among women does not typically lead to the same level of physical violence as it does among men. Moreover, women's sexual jealousy rarely leads to killing of a cheating partner or his lover (Campbell 2004; Fisher and Cox 2010).

Affectively speaking, jealousy has been proposed to be similar to the fight or flight stress response, evoking negative emotions such as anger, fear, distress, and sadness (Buss 2013a; Fernandez and Palestini 2010). Pines and Friedman (1998) reported that sadness by the loss of a romantic bond is more representative of the experience of jealousy in women, which may function to accrue social support from close kin and allies, in times of intense distress, when commitment and support from a partner is lost to a rival (Hrdy 2009). It has been suggested that women's sexual jealousy is more reminiscent of freezing and immobilizing feelings, probably associated with intense fear and sadness, facilitating the recruitment of cognitive resources to cope with the loss (Fernandez and Palestini 2010).

Therefore, it can be expected that women's sexual jealousy in reaction to threats to the pair-bond will differ from the experienced affective states that follow from actually losing a pair-bond to a rival (see Fig. 1). Indeed, recent advances in research on intimate partner violence have hypothesized that aggressive reactions toward the partner are more frequent than commonly thought, with sexual jealousy being one of the main sources of fear that causes women to engage in fierce aggression directed at the partner or a rival, possibly mediated by an oxytocin surge when a highly intense pair bond is threatened (Cross and Campbell 2011).

The Adaptive Function of Women Sexual Jealousy

Sexual jealousy appears to be an emotion that is not independent of deep feelings of attachment toward a romantic partner – on the contrary, the more committed a person is to their partner, the more sexual jealousy she will experience toward rivals (Rydell et al. 2004).

Adaptively speaking, a characteristic of women's reproduction is that diversity of sexual encounters does not increase their reproductive rate, e.g., mating with one or several partners does not raise the number of offspring a woman will bear (Buss 2013b). Therefore, the focus of female jealousy seems oriented toward safeguarding and maintaining the investment from a valuable reproductive partner, which will secure her fitness by maintaining the commitment and resources of the man toward her and their common progeny (Buss 2013a; Symons 1979). Similarly, comparative work on other primates suggests that the presence of social support and alloparenting in the human species (Hrdy 2009) could function to ensure care of one's offspring in the event a partner betrays her and leaves her without resources as well as when a jealous woman attacks the reputation and social support of other women who are perceived as rivals (Campbell 2004; Fisher and Cox 2010).

Sexual Jealousy Among Women, Fig. 1 Activation of women sexual jealousy by a rival and its strategic consequences. When women are faced with a rival, they must initially determine if the rival poses a threat or if the partner has been lost to the rival. If there is a perceived threat, sexual jealousy will motivate women to assess the attractiveness of the rival compared to oneself. If this evaluation

determines that the rival is less attractive, mate retention will probably be the reaction. If the rival is more attractive than oneself, this will activate strong intrasexual competition. If the partner is lost to the rival, women's sexual jealousy will induce sadness and withdrawal, drawing close allies and social support to cope with the loss

Women's sexual jealousy leads to cognitive and behavioral responses that are highly intense in nature and are aimed at preventing the loss of a significant pair-bond (Campbell 2004). Love and care are universally the most effective strategies to retain a partner (Buss 2013b; Salkicevic et al. 2014), probably by signaling the willingness to invest and commit in a long-term relationship with the other person, and the exchange of benefits and caring for the welfare of the partner and offspring (Buss 2013b; Conroy-Beam et al. 2015).

Research based on interviews with the Himba of Namibia, a natural fertility population in which extra pair sexual activity is allowed, suggests that female jealousy in non-Western contexts also functions to prevent the diversion of resources toward other women with whom the partner may father a child (Scelza 2014). In our current context, the function of sexual jealousy is likewise aimed at maintaining men's investment in potential common reproduction. Therefore, sexual and erotic interactions with other women who are perceived as attractive rivals (Buunk and Fisher 2009), as well as more subtle intimate affectionate behaviors, such as sharing hugs, kisses, and cuddling, are prototypical actions that induce women's sexual jealousy in Western societies. And giving large amounts of money to an opposite sex individual, as well as many other forms of investments in rivals, triggers sexual jealousy in female college students (Kruger et al. 2013). Once jealousy is activated, psychological mechanisms assess the context and the characteristics of the opponent to decide whether the response will be directed at the partner, the rival, or both (Buss 2013a).

There are diverse manners in which jealousy motivates mate-guarding behavior, and there are particular strategies and tactics that are differentiated by sex in the realm of mate retention and intrasexual competition (Buss 2013b; Fisher and Cox 2010). One purpose of women's sexual jealousy is to alert the individual to engage in mate retention strategies which are specialized ways to protect the mating bond from rivals (see Fig. 1), such as enhancing the individual's own attractiveness and the benefits they bring to their relationship (with the costs that they will cause if they were to end the relationship). Moreover, women's jealousy

may also motivate distancing and derogating and sometimes physically aggressive behaviors toward the rival (Cross and Campbell 2011).

For example, a very attractive female rival is a stimulus that readily activates jealousy in women across different cultures and contexts (Buunk and Fisher 2009; Dijkstra and Buunk 2002). Attractive rivals lead to a diversity of "strategies" which are deeply rooted in our inherited ancestral wisdom, which ultimately allow one to move the rival away from one's mate and eliminate the threat of partner desertion. A jealous woman may react by enhancing their attractive attributes, bringing costs to the partner (like threatening to break up with him), or removing the partner from the context in which the threat occurs (e.g., by offering to spend quality time together, performing sexual favors, or engaging in love acts or declarations). There are also particular ways in which women may reduce the threat posed by the rival with indirect aggression toward the other woman: derogating her appearance and reputation, isolating the rival from social networks, or as a more radical resource (particularly when males are scarce), women may physically aggress against the rival in order to eradicate the threat (Buss 2013b; Campbell 2004).

The evolved function of women's sexual jealousy is alerting the individual to display mate retention behaviors and/or intrasexual competition, in order to preserve the pair-bond. Directing efforts at minimizing the relevance of the rival with the partner (Fisher 2004), or enhancing self-attractiveness compared to the rival, are some common behaviors to deal with sexual jealousy (Massar and Buunk 2016; Fisher and Cox 2010). Similarly, female intrasexual competitive behaviors are aimed at derogating the rival or directly attacking and distancing the competitor from the partner and are quite frequently motivated by women's jealousy (Cross and Campbell 2011; Grabe et al. 2012).

Female Jealousy Specializations for Detecting Potential Rivals

Sexual jealousy is exacerbated in women of low mate value relative to their high mate value counterparts, and low mate value women tend to

engage more frequently in indirect aggression, which may be caused in the less attractive women by an intensified perception of other women as potential rivals (Campbell 2004; Fisher and Cox 2010; Massar and Buunk 2016). This can be explained, as Fig. 1 shows, because when women encounter other women who are attractive competitors, jealousy gets activated, leading to feelings of the relationship being threatened. Conversely, given that mate-guarding may be less effective in the face of a more attractive rival the best option may be reacting aggressively toward the rival, as well as activating manipulative mate retention tactics, which are enhanced by the sexual jealousy mechanism.

For example, it has been documented elsewhere that sexual jealousy operates by capturing attentional resources such as visual perception, making females who are exposed to attractive women *blind* to other relevant information, possibly favoring the direction of cognitive and affective attention toward the retention of the romantic partner (Most et al. 2010). Likewise, it has been experimentally established that in the context of professional news reporting dynamics, women excel over men in attending to the content of information reported by highly attractive *sexualized* women journalists, which suggests a female specialization for attending to the professionalism and the message of other attractive women, which could be later used with very refined tactics to diminish the threat posed by the rival (e.g., by derogating the content or the intellectual/professionalism of the rival, Grabe et al. 2012).

Massar and Buunk (2009) found that women's sexual jealousy is also dependent on individual differences in jealousy, showing that jealousy leads to intrasexual competition more strongly in women possessing higher levels of basal preventive jealousy, which is characterized by a general tendency to prevent contact of the partner with any other woman. Correspondingly, when priming women with a highly attractive rival, they experience negative feelings (without being conscious of the stimulus). Women of relatively low mate value respond with increased jealousy to subliminally presented rivals flirting with the

partner in any condition, and high mate value females increase their jealousy only when the rivals are portrayed as attractive. In a Chilean study (Fernandez et al. 2014), age has been shown to mediate female jealousy having an inverse association to intrasexual competition, with young women averaging more jealousy and intrasexual competition than women passed their reproductive peak (over 27 years of age).

Similarly, recent findings documented women as significantly more efficient than men at detecting potential cues to infidelity, such as a very attractive woman flirting with a committed man, while there are no sex differences in detecting other kinds of socially threatening stimuli (Ein-Dor et al. 2015).

Women's Mate-Guarding Behavior

One way of dealing with sexual jealousy in both sexes is watching over or guarding a mate, which involves monitoring their social network, removing the mate from potential rivals (see preventive jealousy in Massar and Buunk 2016), trying to monopolize the partner's attention, securing social engagement with the partner, and the like, which are all forms of what has been labelled *mate guarding* (Buss 2013b).

Explorations of women's sexual jealousy relative to the availability of attractive rivals in the mating market has led researchers to posit that female jealousy in high-risk social contexts motivates monitoring and focusing on the partner's behavior in order to detect deception cues more so than focusing on the rival's behavior. On the other hand, when women perceive there is a low-risk social context of same sex rivalry, they tend to center their attention on the rival's characteristics more so than on the partner's deceptive behavior (Hanson et al. 2014).

Women's self-promotion (i.e., augmenting attributes of oneself which are highly valued by men) is a commonly used strategy to retain a partner and outcompete rivals (Buunk and Fisher 2009; Fisher 2004). According to findings of intrasexual competition, when faced with sexual jealousy, women's self-promotion allows them to enhance, imitate, or fake traits that are attractive to men, which increases the probability of driving away partner's

attention from a rival and redirecting it to oneself (Fisher and Cox 2010).

Benenson et al. (2013) found that an effective way that women use for discouraging rivals and distancing them from a valued partner is socially isolating them, which has the advantage of reducing the number of competitors in a given mating context.

Research in the field of evolutionary psychology, as well as the literature on relationship satisfaction and commitment, and mate retention and romantic attachment, has suggested that the delivery of benefits is an optimal mate retention strategy, being more effective than cost-inflicting mate retention tactics. This is to say that giving love and care, enhancing attractiveness, and increasing sexual activity are highly effective female strategies to guard and retain a partner. Threats of ending the relationship and derogating the partner or the partner's close social network may be weaker strategies to retain a mate in face of sexual jealousy (Salkicevic et al. 2014).

Women's Intrasexual Competition and the Green-Eyed Monster

Derogation of Competitors

Women's sexual jealousy motivates in the jealous female intrasexual competitive behaviors directed at enhancing the attractiveness of oneself and derogating the rival (Fisher and Cox 2010). The prevalence of strong intrasexual competition as the result of perceived mating rivalry from other women has been extensively documented in the last couple of decades (as it can be read in more detail in the respective entry of this volume).

Similarly, in the context of being surrounded by women who are perceived as more attractive than oneself, females systematically derogate other women, diminishing their ratings of facial attractiveness of other females (Fisher 2004). Competitor derogation when experiencing sexual jealousy includes making other women less attractive to the eyes of the partner, or enhancing other female's negative attributes, which rises the likelihood that the rival will be perceived as less attractive than oneself, and positing negative attributes of the rival, such as saying that she is unfaithful or that

she has an unattractive body (Campbell 2004; Fisher 2004). As Fisher and Cox (2010) showed, in the face of female sexual jealousy, an attractive woman can benefit more from derogation of rivals, since men give credibility to attractive woman's judgements about other women. But in the context of a jealous, less attractive woman, derogation can be interpreted as envy and even lower the mate value of the woman in relation to the more attractive rival (see the chapter on ► [“Women's Use of Direct Versus Disguised Social Aggression”](#) in this volume).

Women's Aggression in Response to Sexual Jealousy

Jealousy among females activates mate retention behaviors which have been shown to be very specific to the context and circumstances that surround women in particular: in contexts where reproductively valuable men are scarce, women engage in intense indirect as well as direct aggression toward other women, and they can also engage in direct aggressions toward the partner (Cross and Campbell 2011).

Female jealousy motivates aggression toward other women who are perceived as rivals, particularly when self-assessment indicates that there is a high chance that the partner may defect from the relationship for the other woman (Fisher and Cox 2010), or when the rival is significantly more attractive than oneself.

Conclusion

According to current advances in evolutionary psychological science, women's sexual jealousy is an adaptive response to a salient ancestral problem posed by the loss of a valued reproductive partner to another woman. This entry has reviewed the strategic fashion in which women's sexual jealousy orchestrates the feelings, responses, and the behaviors that follow, directed at retaining the pair-bond with the partner and distancing the rival.

One of the main characteristics of women's sexual jealousy is the fine calibration of this psychological feature for attending to the conditions

and the context in which jealousy occurs, which activates different cognitive and behavioral responses for retaining the partner, distancing the rival, or enhancing oneself in the eyes of the partner. These features of women's sexual jealousy suggest its selective attunement to adaptive problems.
